ABSTRACT. Objective. This study was designed to determine whether a relationship exists between previous exposure to measles, mumps, and rubella (MMR) by natural infection or vaccination or by new immunization with MMR vaccine, and either the presence or levels of autoantibodies against thyroid cell and pancreatic β-cell antigens.

Methods. Antibodies against MMR and autoantibodies against thyroglobulin, thyroid peroxidase, pancreas islet cells (ICA), islet cell surface, glutamic acid decarboxylase 65k autoantibodies, and insulin were studied before, and 3 months after, vaccination with combined MMR vaccine in 386 school children between 11 and 13 years of age.

Results. The vaccination changed neither the prevalence nor the level of autoantibodies. Children with rubella antibodies before vaccination had higher levels of ICA than did the rubella seronegative children. In contrast, thyroid autoantibody levels and prevalence were lower in children with antibodies against measles, mumps, or both before vaccination than in children without those antibodies.

Conclusions. Previous natural infection or vaccination against measles, mumps, or both seemed to have an inhibitory effect on the development of thyroid autoantibodies. In contrast, children with previous exposure to rubella had higher levels of ICA. No evidence was found that MMR vaccination during adolescence may trigger autoimmunity. Pediatrics 1999;104(1). URL: http://www.pediatrics.org/cgi/content/full/104/1/e12; autoantibodies, thyroiditis, type 1 diabetes mellitus, vaccination, virus.

ABBREVIATIONS. AIT, autoimmune thyroiditis; Tg-ab, thyroglobulin autoantibodies; TPO-ab, thyroid peroxidase autoantibodies; ICA, pancreas islet cell autoantibodies; GAD65Ab, glutamic acid decarboxylase autoantibodies; IAA, insulin autoantibodies; CRS, congenital rubella syndrome; ICSA, islet cell surface autoantibodies; GAD65Ab, glutamic acid decarboxylase 65k autoantibodies; MMR, measles, mumps, and rubella; IDF, Juvenile Diabetes Foundation; IgG, immunoglobulin G.

In the majority of cases, children with autoimmune diseases such as autoimmune thyroiditis (AIT) or insulin-dependent type 1 diabetes mellitus are characterized by the absence of any first degree relative with the disease in question. The prevalence of autoimmune markers associated with these disorders in children is higher than the prevalence of the respective diseases. It is unclear when and why autoantibodies are acquired and what induces the progress of disease in the individual patient. At clinical diagnosis of AIT, 93% to 95% of the patients have at least one of the thyroglobulin autoantibodies (Tg-ab) or thyroid peroxidase autoantibodies (TPO-ab). Of patients with newly diagnosed type 1 diabetes mellitus, 80% to 90% have islet cell antibodies (ICA), 70% to 80% have glutamic acid decarboxylase autoantibodies (GAD65Ab), and 46% to 70% have insulin autoantibodies (IAA). Virus and other environmental factors have been suggested to be initiators of the autoimmune reactions resulting in disease. Congenital rubella syndrome (CRS) has been reported to be associated with an increased risk of subsequent type 1 diabetes17,18 or AIT.19 Mumps,20,21 coxsackie B3 and B4,22,23 and cytomegalovirus24–26 have also been suggested to be involved in the pathogenesis of type 1 diabetes.

If virus infection has an immunomodulatory effect, there is a possibility that vaccination may also induce autoimmunity, especially when live, attenuated virus is used, as in measles, mumps, and rubella (MMR) vaccination. In contrast to virus as initiating agents, a recent study showed that infections in early life may be associated with a reduced risk of type 1 diabetes.27 Similarly, recently published epidemiologic data imply that BCG vaccination performed neonatally may be associated with lower risk of type 1 diabetes than later vaccination,28 which in turn suggests that the timing of immunization with common pediatric vaccines may be an important determinant of the risk of developing type 1 diabetes.

The present study was designed to determine whether a relationship exists between previous exposure to measles, mumps, or rubella by natural infection or vaccination or new immunization with MMR vaccine, and either the presence or titers of autoantibodies against thyroid cell or pancreatic β-cell antigens.

Statistical Analyses

The \( \chi^2 \) test was used for subgroup comparison of antibody positivity rates, and Fisher’s exact test (two-tailed) was used for comparison of small groups. The Mann-Whitney U test was used for subgroup comparisons of antibody levels among groups, and Student’s t test was used for comparison of antibody levels before and after vaccination. \( P \) values < .05 were considered significant.

This study was approved by the ethics committee of the medical faculty at the University of Lund, Malmö, Sweden.

### RESULTS

#### Autoantibodies and Heredity for Thyroid Disease or Type 1 Diabetes

Relationships between the prevalence of autoantibodies and heredity for thyroid disease or type 1 diabetes are presented in Table 1. Heredity was not a significant correlate of autoantibody prevalence.

#### Autoantibodies and Virus Antibodies Before MMR Vaccination

**Pancreatic Islet \( \beta \)-Cell Autoantibodies**

ICA

The prevalence of ICA positivity was slightly higher in the subgroup with positive IgG-antibodies against measles, mumps, or both than in the corresponding seronegative subgroup, although the difference was nonsignificant (4% [8/190] vs 1% [2/196]; \( P = .06 \)), but ICA levels were significantly higher in the rubella seropositive subgroup.

Statistically significant differences between the virus seropositive and seronegative groups are denoted by asterisks: * (P < .05) or ** (P < .01).

If thyroid autoantibodies were present in a titer of 5 or more, the sample was considered positive.

subgroup (mean 5.9 JDF units vs mean 1.6 JDF units; P < .05, Mann-Whitney U test). There was no difference in the prevalence of ICA positivity among the subgroups seropositive versus seronegative for either measles or mumps.

GAD65Ab, IAA, or ICSA

There was no difference in the prevalence of GAD65Ab, IAA, or ICSA positivity among the subgroups seropositive for mumps, measles, or rubella versus the corresponding seronegative subgroup.

Virus Antibodies Before and After MMR Vaccination

The pre-MMR and post-MMR vaccination prevalences of IgG antibody positivity in reference to MMR are given in Table 3. All subjects became seropositive after vaccination with the exception of 5% (19/386) who remained seronegative against the mumps antigen. There was no significant gender-related difference in the pattern of viral antibody positivity.

Autoantibodies Before and After MMR Vaccination

The pre-MMR and post-MMR vaccination autoantibody positivity prevalences are shown in Table 4. No significant difference was found in the prevalence of positivity in reference to any of the autoantibodies before versus after vaccination. MMR vaccination did not affect either the prevalence of autoantibody positivity or the levels of autoantibodies.

DISCUSSION

This study showed both the prevalence of thyroid autoantibody positivity and the titers to be lower among individuals with IgG antibodies against measles, mumps, or both, acquired by previous exposure attributable to either natural infection or vaccination. We also found the levels of ICA to be higher in the rubella IgG-positive than in the rubella-negative subgroup. MMR vaccination had no effect on the prevalence of either thyroid or islet autoantibody positivity (ICA, IAA, GAD65Ab, or ICSA). Heredity for AIT or type 1 diabetes did not correlate to the prevalence of the respective autoantibodies.

The relationship found between thyroid autoantibody (Tg-ab + TPO-ab) negativity and the presence of virus antibodies suggest that previous virus exposure may reduce autoreactivity. The opposite view is often taken, and it is a popular hypothesis that previous infection induces autoreactivity by means of molecular mimicry.38 Our data, which suggest that the absence of any marker for previous virus infection is associated with increases both in the prevalence of thyroid autoantibody positivity and in the antibody titers, are novel. Although long-term follow-up is needed to determine whether the noninfected children with autoantibodies will develop thyroid disease subsequently, it is open to speculation whether infections with mumps or measles may result in polyclonal activation, which generates regulatory T cells that prevent the survival of autoreactive T cells. To the best of our knowledge, there have been no epidemiologic investigations of the relationship between early MMR infections or vaccination and thyroid disease. At present, we can only speculate that the lower prevalence of thyroid antibody positivity among virus antibody-positive 12-year-old children will be associated with a lower incidence of autoimmune thyroid disease later in life.

In contrast, in type 1 diabetes, a protective effect of early virus infection has been suggested by findings in an epidemiologic investigation.29 Similarly, a case-control study showed the relative risk of developing type 1 diabetes to be reduced in children vaccinated against measles.39

No child seropositive before vaccination converted to seronegativity.
Although the evidence of virus infection before the clinical onset of type 1 diabetes is substantial, the mechanisms by which virus may cause injury to endocrine cells are not understood fully. The prevalence of type 1 diabetes among individuals with CRS is high (12%–20%), although the diabetes may take 5 to 20 years to manifest. Other autoimmune manifestations in CRS include AIT and Addison’s disease. In addition, as with CRS, enterovirus infection during pregnancy is a risk factor for type 1 diabetes in the child.

Early reports were published of the occurrence of type 1 diabetes during acute mumps infection or in the recovery phase, and more recently there have been reports of increasing prevalences of ICA positivity and even type 1 diabetes after vaccination against mumps. Some type 1 diabetes patients have increased levels of specific virus antibodies (e.g., coxsackie B-IgM and rubella) and PCR-detected coxsackie B3 or B4 genome was reported to be increased among newly diagnosed type 1 diabetes patients. Coxsackie virus antigens have also been observed in the islets of Langerhans. At least one rubella antigen has been shown to react with sera from patients with newly diagnosed type 1 diabetes.

However, direct causative effects have been difficult to verify, and islet autoantibodies may already be present in cord blood from children who later develop type 1 diabetes, suggesting that the islet autoreactivity developed before virus infection. Recent analysis of islets from new onset type 1 diabetic children failed to detect virus DNA or RNA. The difficulty in identifying viruses as etiologic agents in autoimmune disease may be partly explained by our finding that autoreactivity may be modulated by previous virus exposure.

Similar to a previous finding of an increased prevalence of ICSA positivity among cases of CRS, we found rubella-seropositive children to have higher ICA levels than do rubella-seronegative children. This finding may imply the existence of a link between rubella and islet autoimmunity but does not constitute an argument against rubella vaccination, because the value of vaccination for protecting children from CRS is undisputed. A transient increase in the prevalence of ICA positivity, occurring 6 weeks after rubella vaccination but no longer apparent 18 months later, has been reported. However, in our study, as in other studies, the prevalence of ICA positivity was unaffected by MMR vaccination and inconsistent with mumps vaccination being an initiator of type 1 diabetes. However, age at vaccination may possibly be an important factor.

Because we found no difference between pre-MMR and post-MMR vaccination prevalences of autoantibody positivity or in the respective autoantibody titers, our study yielded no evidence that MMR vaccination may trigger autoimmunity in children. Moreover, the lower prevalence of thyroid autoantibody positivity and the lower thyroid autoantibody titers in the subgroup manifesting IgG-antibody positivity in reference to measles and mumps, compared with the corresponding seronegative subgroup, suggest that virus immunization may have a protective effect against thyroid autoimmunity.
