ABSTRACT. Objective. To evaluate maternal and neonatal plasma concentrations of acetylsalicylic acid and salicylic acid and the neonatal endogenous prostanoid formation during low-dose aspirin prophylaxis (LDA; 100 mg daily) in pregnant women.

Methods. Concentrations of acetylsalicylic acid and salicylic acid in maternal plasma after at least 4 weeks of LDA (n = 14) and in umbilical cord plasma of newborns after maternal LDA (n = 7) were determined by gas chromatography–mass spectrometry. Platelet and renal formation of thromboxane A2 and the formation of prostaglandin E2 and prostacyclin were evaluated in vivo by quantification of index metabolites in plasma and urine by gas chromatography–mass spectrometry in neonates after maternal LDA (n = 14) and in a control group.

Results. In the pregnant women, acetylsalicylic acid and salicylic acid concentrations rapidly increased after ingestion of LDA. Acetylsalicylic acid was completely eliminated within 4 hours, whereas salicylic acid was detected with low concentrations at 18 and 21 hours after dosing. In the neonates, acetylsalicylic acid was not detected. Salicylic acid was detected in 1 infant only. Platelet thromboxane A2 formation in the newborn infants was significantly suppressed but recovered within 2 to 3 days after discontinuation of LDA. Renal thromboxane A2 formation and the formation of prostaglandin E2 and prostacyclin were not affected by LDA.

Conclusion. In pregnant women who are treated with LDA, acetylsalicylic acid is not completely inactivated in the portal circulation but reaches the uteroplacental circulation and exerts antplatelet effects in the fetus and newborn. Low-Dose Aspirin in Pregnancy: Maternal and Neonatal Aspirin Concentrations and Neonatal Prostanoid Formation

Andreas Leonhardt, MD*; Stefanie Bernert, MD*; Bernhard Watzer*; Gabriele Schmitz-Ziegler, MD‡; and Hannsjörg W. Seyberth, MD*

METHODS

Patients and Control Subjects

Pregnant women and their newborn infants were included in the study when the women had been treated with 100 mg of aspirin daily for prevention of preeclampsia. The women started LDA prophylaxis at 14 to 33 (median: 20) gestational weeks. Because of anesthesiological concerns, LDA was discontinued before the expected parturition to preserve the possibility of performing an epidural anesthesia, which was considered to be otherwise associated with an increased risk of hemorrhage. Therefore, the number of days from discontinuation of LDA to delivery differed between the newborns. This procedure enabled us to evaluate the relationship between alterations in neonatal prostanoid formation and the number of days without LDA. Because 21% of women in LDA trials are noncompliers,22 urinary excretion of 2,3-dinor-TXB2, reflecting platelet TxA2 formation,23 was measured while the women were still treated with LDA and was compared with the urinary excretion of 2,3-dinor-TXB2 in healthy pregnant women matched for gestational age (±10 days). Only newborn infants of mothers with complete inhibition of
and dried under a gentle stream of dry nitrogen. The sample was fused silica capillary column (DB-5; 20 m was conducted on a Finnigan MAT TSQ45 GC-MS (Finnigan was injected into the GC-MS/MS system. GC-MS/MS analysis were measured after at least 4 weeks of LDA treatment. In a hydrogensulfate (phase-transfer catalyst), 10/H9262 Plasma 11-dehydro-TxB2 and urinary prostanoid metabolites were observed. The intra-assay accuracy was less than ±10% bias from the nominal concentration. The interassay precisions (day-to-day variability) were <15% (coefficient of variation) for acetylsalicylic acid and salicylic acid.

Statistical Analysis

Continuous data were assessed for normal distribution with normal plots and the Shapiro-Francia W test. Nonparametric statistical methods were used because not all variables were normally distributed. Data were expressed as the median (25th, 75th percentiles) unless otherwise stated. The primary study parameters were urinary excretion of 2,3-dinor-TxB2 and plasma concentrations of 11-dehydro-TxB2 in the newborns. Urinary excretion of TxB2 and of PGE2 and prostacyclin index metabolites were secondary study parameters analyzed exploratorily. Comparisons of the medians of 2 groups were performed by the Mann-Whitney U test. The relationship between continuous variables was analyzed by Spearman rank correlation. P < .05 was considered significant. All analyses were performed with use of StatView software 5.0 (SAS Institute Inc, Cary, NC).

RESULTS

Patient Characteristics

Fourteen newborn infants and their mothers were included in the study. The infants were born at 36 to 42 (median: 40) gestational weeks. Birth weight was 3455 g (3280 g; 3720 g). All infants were healthy. In particular, no hemorrhage or clinical signs of impaired platelet function were observed. Intracranial hemorrhage was excluded by cerebral ultrasound.

Plasma Concentration of Acetylsalicylic Acid and Salicylic Acid

In the pregnant women, plasma concentrations of acetylsalicylic acid and salicylic acid increased rapidly after ingestion of LDA (Fig 1). The highest plasma levels of acetylsalicylic acid (4210 ng/mL) and salicylic acid (7928 ng/mL) were measured after 30 and 75 minutes, respectively. Four hours after ingestion of LDA, acetylsalicylic acid was no longer detectable. Plasma concentrations of salicylic acid were 59 and 64 ng/mL after 18 and 21 hours, respectively. Plasma concentrations of acetylsalicylic acid and salicylic acid were measured in umbilical cord blood in a subgroup of 7 newborns. The infants’ mothers had discontinued LDA 1 to 13 days (median: 3 days) before delivery. Acetylsalicylic acid was not detected in any of the samples. Salicylic acid (39 ng/mL) was detected in 1 infant. This infant’s mother had discontinued LDA 1 day before delivery.
Formation of Platelet TxA_2 in Pregnant Women During LDA

In all women, platelet TxA_2 formation was evaluated by measuring the urinary excretion of 2,3-dinor-TxB2 1 to 18 days (median: 6 days) before parturition and while the women were still taking LDA. Urinary excretion of 2,3-dinor-TxB2 was lower in the pregnant women who had been treated with LDA as compared with healthy, untreated pregnant women (3.8 ng/h/1.73 m^2 [2.4 ng/h/1.73 m^2; 5.4 ng/h/1.73 m^2] vs 26.8 ng/h/1.73 m^2 [23.2 ng/h/1.73 m^2; 31.6 ng/h/1.73 m^2]; P < .0001). Urinary excretion rates of 2,3-dinor-TxB2 of the 2 groups did not overlap (range: 2.0–7.1 and 11.1–53.3 ng/h/1.73 m^2 in the LDA and control groups, respectively). This indicates complete inhibition of platelet TxA_2 formation at the time of the investigation.

Formation of Prostanoids in the Newborn Infants

Plasma concentrations of 11-dehydro-TxB2 were measured in umbilical cord blood of a subgroup of 7 newborns. The infants’ mothers had discontinued LDA 1 to 13 days before delivery. 11-dehydro-TxB2 correlated with the days without LDA aspirin (r^2 = 0.88, r = 0.94, P = .02; top) and was lower in the newborns after maternal LDA than in the control subjects (P = .01; bottom). The broken line in the top panel indicates the fifth percentile of the control group.

DISCUSSION

We found an inhibition of platelet TxA_2 formation in neonates of pregnant women who had been treated with 100 mg of aspirin daily. Both acetylsalicylic acid and salicylic acid were detected in the plasma of the pregnant women in considerable amounts. At birth, plasma acetylsalicylic acid was below the detection limit in all newborns, and salicylic acid was detected in a very low concentration in 1 infant only.

Plasma concentrations of acetylsalicylic acid and salicylic acid measured in the present investigation largely agree with published pharmacokinetic data of both compounds in healthy adults and in pregnant women after a single aspirin dose. It has been assumed that during LDA prophylaxis in preg-
nant women only very little acetylsalicylic acid reaches the uteroplacental circulation and may subsequently be transported across the placenta into the fetal compartment because acetylsalicylic acid is almost completely inactivated in the portal circulation.\textsuperscript{40} The results of the present investigation, however, definitely indicate that the fetus is exposed to acetylsalicylic acid and salicylic acid during LDA prophylaxis in pregnancy.

Ex vivo studies indicate that acetylsalicylic acid readily crosses the placenta.\textsuperscript{12} The placental transfer of salicylic acid has been demonstrated in vivo.\textsuperscript{39,40} After chronic ingestion of acetylsalicylic acid in antiinflammatory doses, plasma concentrations of salicylic acid are higher in the newborn infants than in the mothers because the protein binding of salicylic acid is considerably higher in neonatal than in maternal plasma.\textsuperscript{39,40} Newborn infants mainly eliminate salicylic acid by conversion to the glycine and glucuronic acid conjugates.\textsuperscript{40} The capacity of these pathways is very low, and elimination of salicylic acid by newborn infants is, therefore, much slower than in adults with a half-life of approximately 4 to 11 hours.\textsuperscript{40} Against this background, salicylic acid might accumulate in the fetus and might therefore be detectable in the neonate. In the newborns studied, however, salicylic acid was detected with a very low concentration in umbilical cord blood in only 1 infant, whose mother had ingested the last aspirin dose 1 day before delivery. This suggests that the concentration of salicylic acid in the fetus is actually very low during maternal LDA. On the basis of a neonatal to maternal plasma salicylic acid concentration ratio of 1.6\textsuperscript{39} and a maternal trough level of salicylic acid of approximately 50 ng/mL as suggested by the present study, an estimate of the resulting fetal plasma concentration of salicylic acid is <100 ng/mL.

Although acetylsalicylic acid concentrations were high in the pregnant women, the drug was not detected in any of the newborn infants studied 24 hours or more after the last maternal LDA. The concentrations of acetylsalicylic acid in the systemic and uteroplacental circulation of pregnant women, however, obviously result in substantial amounts of acetylsalicylic acid that cross the placenta and exert antiplatelet activity in the fetus. This assumption is confirmed by the analysis of the endogenous prostanoid formation in the newborn infants, which demonstrates the typical pattern of prostanoid formation during LDA treatment. The formation of platelet \( \text{TXA}_2 \) is selectively inhibited, whereas the renal \( \text{TXA}_2 \) formation and the formation of \( \text{PGI}_2 \) and prostacyclin are not affected. The inhibition of platelet \( \text{TXA}_2 \) formation cannot be ascribed to the placental transfer of salicylic acid, because even the administration of high doses of salicylic acid (1200 mg daily) has no effect on platelet \( \text{TXA}_2 \) formation.\textsuperscript{41} Benigni et al\textsuperscript{15} demonstrated that treating pregnant women with 60 mg of aspirin daily resulted in a 63% reduction of the ex vivo capacity of neonatal platelets to release \( \text{TXA}_2 \) in umbilical cord blood. Valcamonico et al\textsuperscript{18} and Regan et al\textsuperscript{16} obtained similar results. The ex vivo capacity of platelet \( \text{TXA}_2 \) formation, however, is considerably greater than the actual in vivo biosynthetic rate.\textsuperscript{21} We therefore measured the plasma 11-dehydro-\( \text{TxB}_2 \) concentration and the urinary 2,3-dinor-\( \text{TxB}_2 \) excretion. Both compounds reflect the in vivo formation of platelet \( \text{TXA}_2 \).\textsuperscript{21,23} Thus, maternal LDA inhibits the actual in vivo formation of \( \text{TXA}_2 \) in the fetus and neonate.

Plasma 11-dehydro-\( \text{TxB}_2 \) was clearly lower in the newborns after maternal LDA than in the control subjects. The difference between the 2 groups was less pronounced with respect to urinary 2,3-dinor-\( \text{TxB}_2 \) excretion. The different inhibition of platelet \( \text{TXA}_2 \) formation as assessed by plasma 11-dehydro-\( \text{TxB}_2 \) and urinary 2,3-dinor-\( \text{TxB}_2 \) is probably attributable to the shorter period of time that elapsed since the last ingestion of aspirin by the mothers in the newborns with analysis of plasma 11-dehydro-\( \text{TxB}_2 \) (median: 3 days) as compared with the newborns with analysis of urinary 2,3-dinor-\( \text{TxB}_2 \) (median: 5.5 days). The correlation between plasma 11-dehydro-\( \text{TxB}_2 \) in umbilical cord blood and the days without LDA indicates rapid recovery of platelet \( \text{TXA}_2 \) formation. Already 2 to 3 days after the infants’ mothers had ingested the last aspirin dose, plasma 11-dehydro-\( \text{TxB}_2 \) in the newborns exceeded the fifth percentile of plasma 11-dehydro-\( \text{TxB}_2 \) in the control subjects (Fig 2). Valcamonico et al\textsuperscript{18} and Benigni et al\textsuperscript{15} demonstrated recovery of the ex vivo capacity to form platelet \( \text{TXA}_2 \) in neonates after LDA within 4 and 5 days. These findings are consistent with the idea that inhibition of platelet \( \text{TXA}_2 \) formation by aspirin is attributable to irreversible acetylation of platelet cyclooxygenase and will recover with the production of unaffected platelets. The results also indicate that during LDA and until 2 to 3 days after the last aspirin dose, platelet function may be impaired in the fetus and newborn infant.

Inhibition of platelet \( \text{TXA}_2 \) formation in the fetus and neonate as observed in the present study may be clinically relevant. Ingestion of aspirin in analgesic or antiinflammatory doses a few days before delivery is associated with bleeding complications in the newborn infant.\textsuperscript{13,14} In contrast, major hemorrhage was not observed in the large number of infants who were born after LDA prophylaxis in pregnancy.\textsuperscript{1,42,43} In adults, inhibition of the capacity to form \( \text{TXA}_2 \) must be virtually complete (>95%) before Tx-dependent platelet activation is influenced in vivo.\textsuperscript{44,45} Neither the previously published studies\textsuperscript{15,16,18} nor the findings of the present study support the assumption of complete inhibition of fetal or neonatal platelet \( \text{TXA}_2 \) formation by LDA in pregnancy when aspirin doses up to 100 mg daily are used. It has been suggested that a higher aspirin dose might possibly be more effective in the prevention of preeclampsia.\textsuperscript{4,46,47} Considering, however, the inhibition of platelet \( \text{TXA}_2 \) formation already present in the neonates after 100 mg of aspirin daily and the dose-dependent decline of platelet \( \text{TXA}_2 \) formation when aspirin doses of 20 to 325 mg/d are ingested,\textsuperscript{11} increasing the aspirin dose will result in a more pronounced inhibition of platelet \( \text{TXA}_2 \) formation, which may be associated with an increased risk of fetal and neonatal hemorrhage.
