PARENTAL MANAGEMENT OF ASTHMA TRIGGERS WITHIN A CHILD'S ENVIRONMENT

Purpose of the Study. To assess the type and frequency of attempts by families to control environmental precipitants of asthma symptoms and their degree of consistency with current National Heart, Lung, and Blood Institute (NHLBI) asthma guidelines.

Study Population. A nationwide sample of 896 children (ages 2–12 years) with asthma who had used asthma-related health care within the previous 2 years. Patients were selected randomly from the panels of 106 primary care clinicians participating in a trial to evaluate the effect of physician asthma education on health care utilization.

Methods. A cross-sectional, telephone-based survey was conducted. Respondents were asked open-ended questions to identify triggers for their child's asthma and to describe specific actions taken to eliminate these triggers in the home. Demographic and environmental modification underscores the importance of education and encouragement in all families.

INCCREASED PREVALENCE OF LATEX-SENSITIZATION AMONG CHILDREN WITH CHRONIC RENAL FAILURE

Purpose of the Study. To assess the prevalence of latex sensitization and identify risk factors for latex sensitization among children with chronic renal failure.

Study Population. Ninety-three patients (44 boys and 49 girls; median age: 10.5 ± 6.0 years) with chronic renal failure who presented to the University of Vienna Children’s Hospital Nephrology Clinic between 1997 and 2000.

Methods. Latex sensitization was assessed by a questionnaire-based history and measurement of total and latex-specific serum IgE by solid-phase immunoassay. Patients and parents were queried regarding the etiology of renal failure, age at onset, number of renal transplantations, surgical procedures, hemodialysis, clinical symptoms with latex exposure, personal and family history of allergy, and history of pacifier use. Patient responses were compared with medical histories and were consistent. Patients were designated as latex sensitized if their latex-specific serum IgE was ≥0.35 kilounits of allergen-specific IgE per liter (kU/L). Neither skin-prick testing nor provocation testing was performed.

Results. Of the 93 patients enrolled, 10 (10.8%) were found to have latex-specific IgE levels (0.35–9.44 kU/L). Of those, only 1 patient reported clinical symptoms on latex exposure compared with 4 patients with no demonstrable latex-specific IgE. No reactions to latex were reported to occur during medical care. A personal or family history of allergy, a greater number of urogenital surgeries, and hemodialysis were reported more frequently in latex-sensitized children. Gender, age at enrollment, age at first urogenital surgery, renal transplantation, and the use of pacifiers did not differ between latex-sensitized and -nonsensitized children.

Conclusions. The prevalence of latex sensitization among children with chronic renal failure is greater than that previously reported for the general pediatric population (10 of 93 vs 8 of 1175 in an unselected pediatric population). Eight of the 10 sensitized patients in this study had renal disease diagnosed within the first year of life and therefore had early and repeated exposures to latex. The small sample size prevented detection of significant associations with any determinant of renal disease or definite risk factor for sensitization.

Reviewers’ Comments. Atopy and repeated exposure to latex allergen have been previously associated with sensitization to latex. Children with chronic renal failure are frequently exposed to latex and therefore are likely at increased risk. A larger study population would be required to further characterize this increased risk. This study raises interesting questions regarding the impact of both timing and cumulative amount of latex exposure for all children with chronic illnesses.

FOOD ALLERGY

PREVALENCE OF PEANUT AND TREE NUT ALLERGY IN THE UNITED STATES DETERMINED BY MEANS OF A RANDOM DIGIT DIAL TELEPHONE SURVEY: A 5-YEAR FOLLOW-UP STUDY

Purpose of the Study. To determine the prevalence of self-reported peanut and tree-nut allergy among the general population of the United States in 2002 and compare it with prevalence rates obtained 5 years earlier.

Study Population. A total of 4855 households representing a census of 13 493 participated.

Methods. A nationwide, cross-sectional survey was administered by telephone to persons called by a random sampling of telephone numbers in the continental United States. Adults acted as surrogates for minors with peanut or tree-nut allergy. Differences in responses between groups were tested by χ² analysis.

Results. Fifty-three percent of contacted homes participated. Peanut allergy, tree-nut allergy, or both was self-reported in 166 (1.2%; 95% confidence interval [CI]: 1.0%, 1.4%) individuals in 155 (3.2%; 95% CI: 2.7%, 3.7%) households. These prevalence rates were similar to those reported in 1997. Any differences in prevalence rates between people of different race/ethnicity did not reach statistical significance. There was an overall male predominance of peanut or tree-nut allergy in children (P = .02) and a female predominance in adults (P = .0008). The prevalence of reported peanut allergy among children increased significantly from 0.4% in 1997 to 0.8% in 2002 (P = .05), but the rate of tree-nut allergy did not change significantly. The prevalence of peanut and tree-nut allergy in adults did not change significantly between 1997 and 2002. Overall, the adjusted prevalence rate taking into account individuals with reported allergy without convincing histories was 1.04% (95% CI: 0.9%, 1.2%). Of the reported reactions, 79% involved either respiratory symptoms or multiple organ systems. Only 74% of children and 44% of adults were evaluated by a physician for their allergic reactions, and self-injectable epinephrine was prescribed for 46% of the children and 23% of the adults.

Conclusions. The authors reported similar overall rates of peanut and tree-nut allergy in the United States, as was noted in 1997, but over this 5-year period the prevalence of peanut allergy in children doubled.

Reviewers’ Comments. The findings of increased prevalence of peanut allergy may be expected with the well-documented increase of atopic diseases in the past decades. Why the prevalence of tree-nut allergy would be unchanged during this same period will require additional investigation. A notable finding in this study is that >25% of children and 50% of adults who reported peanut or tree-nut allergy did not seek medical evaluation. Even more remarkable is that after medical evaluation for peanut or tree-nut allergy, self-injectable epinephrine was prescribed to approximately half of the children and less than one quarter of the adults. This underscores the need for continued improvement in the care of patients with food allergy, which is increasing in prevalence.

PEANUT ALLERGY: RECURRENCE AND ITS MANAGEMENT

Purpose of the Study. To determine the rate of peanut allergy recurrence, identify risk factors for recurrent peanut allergy, and develop specific recommendations for the treatment of patients with resolved peanut allergy.

Study Population. Children >4 years old with prior diagnosis of peanut allergy who had undergone and passed an oral peanut challenge.

Methods. Children were evaluated by using questionnaires, skin tests, and peanut-specific IgE levels. Patients were invited to undergo a double-blind, placebo-controlled food challenge (DBPCFC) unless the history of a possible recurrence reaction was so convincing that a challenge would be potentially dangerous.

Results. Sixty-eight patients were evaluated. Forty-seven patients continued to tolerate peanut, of whom 34 ingested concentrated peanut products at least once per month and 13 ate peanut infrequently or in limited amounts but passed a DBPCFC. The status of 18 patients was indeterminate because they ate peanut infrequently or in limited amounts and declined to have a DBPCFC. After excluding 12 patients originally diagnosed with peanut allergy based solely on a positive skin-prick test or peanut-specific IgE level, 3 of 15 patients who consumed peanut infrequently or in limited amounts had recurrences, compared with no recurrences in the 23 patients who ate peanut frequently (P = .025). The recurrence rate was 7.9% (95% confidence interval: 1.7%, 21.4%).

Conclusions. Children who outgrow peanut allergy are at risk for recurrence, and this risk is significantly higher for patients who continue largely to avoid peanut after resolution of their allergy. It is recommended that patients eat peanut frequently and carry epinephrine indefinitely until they have demonstrated ongoing peanut tolerance.

Reviewer’s Comments. Recent studies reported that up to 20% of peanut-allergic children may outgrow this condition, giving hope to many patients. Follow-up of the children who passed an oral peanut challenge showed that some children experienced acute allergic reactions to peanut some time after having passed a challenge. Children avoiding peanut were more likely to have recurrence of their peanut allergy than those ingesting peanut on a regular basis. The possibility of recurrence of peanut allergy and importance of regular dietary peanut intake should be discussed with patients and their parents when considering oral peanut challenges. It should be noted that recurrence has been reported solely for peanut and fish allergy, whereas recurrence of other food allergies such as those to cow’s milk, egg, soy, or wheat have not been described in the literature.

DISTRIBUTION OF PEANUT ALLERGEN IN THE ENVIRONMENT

Purpose of the Study. To determine the amount of peanut protein detectable in a variety of common exposure settings and examine the effectiveness of measures used to clean peanut from tables and hands.

Methods. A monoclonal-based enzyme-linked immunosorbent assay was used to detect 1 of the major peanut proteins (Ara h1) from surface-wipe samples of hands, tables, and other surfaces and from air samples.

Results. After purposeful handling of a teaspoon of peanut butter, hand-washing with liquid soap, bar soap, or commercial wipes resulted in no detectable Ara h1. However, using plain water without soap or an antibacterial hand sanitizer left detectable Ara h1 on 3 of 12 and 6 of 12 hands, respectively. Purposeful placement of a teaspoon of peanut butter on 1 square foot of tabletop followed by
