Congenital Fibrosarcoma and History of Prenatal Exposure to Petroleum Derivatives

abstract

Congenital fibrosarcoma (CFS) is a rare fibrous tissue malignancy that usually presents in the first few years of life. It is unique among human sarcomas in that it has an excellent prognosis. We describe a temporal clustering of a number of cases of CFS and investigate the possible associated prenatal risk factors. The Pediatric Environmental History, a questionnaire developed in our clinic that is instrumental in determining environmental risk factors for tumor-related disease, was essential in documenting the presence or absence of risk factors considered as human carcinogens. We found a history of exposure to petroleum products in four cases of CFS that occurred at a greater than expected rate in a short time frame—an apparent cancer cluster. We call attention to the possibility that exposure to petroleum products raises the risk of developing CFS. While future studies should focus on systematic investigation of CFS and its underlying mechanisms, this report suggests the need for proactive measures to avoid exposure to solvents and petroleum products during pregnancy.

Congenital fibrosarcomas (CFS) are soft-tissue sarcomas diagnosed at or soon after birth and represent ~5% to 10% of all sarcomas occurring in infants <1 year. With an estimated incidence of 3.7/million live births, CSF presents typically a ETV6-NTRK3 gene fusion as a result of a t(12;15)(p13;q25) translocation. The chromosomal translocation may arise as a result of unfaithful repair of spontaneous DNA double-strand breaks, most probably induced by oxidative stress, radiation, or genotoxic chemicals. Although no chemical carcinogen has been identified to date, several risk factors have been associated with soft-tissue sarcomas in children: congenital anomalies, genetic conditions (Li-Fraumeni syndrome and neurofibromatosis type 1), low socioeconomic status, ionizing radiation (in utero), and parental use of marijuana and cocaine during the pregnancy. The Integrated Risk Information System is a US Environmental Protection Agency database of potential health effects from environmental substances focusing on hazard identification and dose-response and carcinogenicity assessment. With the use of this system, we identified 16 substances associated with fibrosarcoma (Table 1). Only one, dibenz[a,h]anthracene, is likely a human carcinogen. The identified risk factors for infantile fibrosarcoma are unknown. The Pediatric Environmental History (PEH) questionnaire is a tool that allows for the registration of environmental risk factors related to tumor disease (Table 2). We report a suspected cluster of 4 CFS cases and illustrate the potential utility of PEH in identifying risk factors for CFS.

**METHODS**

**Patients and Study Design**

Medio Ambiente y Cáncer Pediátrico–Environment and Pediatric Cancer Group is a project for the compilation of PEH in patients newly diagnosed with cancer since 2001. Centralized care in pediatric oncology referral units in Spain facilitated the access to the medical records in the La Fe University/Children’s Hospital, the Valencia University Hospital, and the General University Hospital of Alicante, which register 100% of the children diagnosed with cancer in the Valencian Community (population 4.5 million in 2004). Three cases of CFS were verified, raising the suspicion that there is an excess of cases for that short time period. The presence of these cases led to a careful review of the hospital registries and data from the hospital collaborating in this survey back to 2001 of all the children diagnosed with fibrosarcoma <5 years of age.

We studied a suspected cluster of 4 cases of CFS in the greater Valencia region in Spain (Fig 1). All of the CFS cases were diagnosed between 2001 and 2004 and were registered in the Regional Registry of Tumors and in the database of hospitals collaborating in this survey (reaching >99% of area cases).

The first case of CFS was diagnosed in 2001 in Castellon, 2 cases were diagnosed in 2004 in Valencia, and 1 was diagnosed in the nearby Xativa. All the cases corresponded to the anatomicopathological diagnosis of CFS in newborns (located in the abdominal, facial, forearm, and thigh regions) and had the t(12;15)(p13;q25) translocation, typical of CFS.

Expected cases for live children were calculated by using the Autonomic Community of Valencia as reference population. The incidence of CFS is estimated to be 3.7 cases/million in newborns, up to 8 cases/million in children <1 year of age and 2 cases/million in children <5 years of age.

To evaluate the risk, we used the standardized incidence ratio with a 95% confidence interval. The Scan statistic test was used for identifying temporal, spatial, and spatiotemporal clusters.

**Exposure Data: Pediatric Environmental History**

The PEH tool comprises a series of concise and basic questions formulated to identify environmental exposures of concern and to document human carcinogens characterized by the International Agency for Research on Cancer (IARC) and by the US National Toxicology Program. The PEH questionnaire is applied to all patients with cancer and all pediatric consultations at the Pediatric Environmental Health Specialty Unit. The interview is a structured or semistructured process, a standardized form is used, and the questions are either open ended or multiple choice. The interview was conducted, in person, by 1 pediatrician with one or both parents present. Informed consents were obtained from the parents participating.

Chemical Carcinogenesis Research Information System, a database sponsored by the National Cancer Institute containing data on carcinogens, mutagens, and tumor promoters, was reviewed, documenting registered chemical substances associated with fibrosarcoma. The La Fe University/Children’s Hospital ethics committee and the institutional review boards approved the study.

**Case Reports**

**Patient 1**

A male patient born at 37 weeks of pregnancy, 3500 g. Retroperitoneal neonatal fibrosarcoma was detected at 34 weeks of pregnancy. Patient did not show any malformations at birth and died at 48 hours because of surgical complications. There was no family history of cancer of first- and second-degree relatives. The mother was primigravida, a nonsmoker and...
nondrinker, worked in a family-owned gas station during pregnancy, being exposed to petroleum derivatives by inhalation. The mother used Bondex (nalfa, 3-butoxy-2-propanol) polish in the home during the second trimester of pregnancy. She worked as a gas-station attendant and at the office for 40 hours/week without using any protection. A chest radiograph was performed on day 11 of pregnancy because of an anxiety crisis.

**Patient 2**

A female patient born at 40 weeks of pregnancy, 3300 g. Mother experienced a diet-controlled gestational diabetes. On delivery, patient was found to have a fibrosarcoma in the right thigh and no malformations. There was no family history of cancer of first- and second-degree relatives. The patient was the first pregnancy for the mother. Both parents smoked during the pregnancy.

EPA, Environmental Protection Agency

\(a\) IARC classification: group 1, carcinogenic to humans; group 2A, probably carcinogenic to humans; group 2B, possibly carcinogenic to humans; group 3, unclassifiable as to carcinogenicity in humans; group 4, probably not carcinogenic to humans.

**TABLE 2** Main Sections of the Pediatric Environmental History\(d\)

Family history and associated constitutional symptoms
- Pedigree of at least 3 generations for:
  a. History of cancer in the family tree
  b. Genetic and constitutional factors associated with childhood cancers
  c. Chronic, rare and family diseases
  d. Causes of death

Detailed description of sources of exposure during pregnancy
- Maternal grandmother’s (maternal egg formation) work during pregnancy and drugs in pregnancy
- Maternal grandfather’s work during pregnancy

Environmental exposures (preconceptional, conceptional, pregnancy, postnatal)

The data collection is distributed in the following sections:
1. General (affiliation and identification, and socioeconomic data), housing (before, during pregnancy, and postnatal), tobacco (before, during pregnancy, and postnatal), external environment (neighborhood, daycare, school), lifestyle during pregnancy and postnatal care, perceptions (before, during pregnancy, and postnatal)
2. Nutrition during pregnancy and exercise
3. Obstetric history (drugs, diseases, etc)
4. Radiologic history of the parents
5. Work history (both parents)
6. Background of the child (birth, neonatal, radiation history, diseases, vaccines, treatments, etc)
7. Breastfeeding
8. Nutrition of the child, exercise, and lifestyle

Type of tumor (tumor data, diagnosis, treatment, and evolution)
and did not consume alcohol. Mother was not exposed to ionizing radiation. The father, a mechanic, was exposed to substances used in cleaning industrial and automobile compressors. The mother worked as a gas-station attendant without using any protection for 40 hours/week for 2 years before conception and during the pregnancy and was exposed to gasoline derivatives via inhalation and dermal pathways.

Patient 3
A female patient, born at 38 weeks at 3560 g. Patient did not show any malformations at birth. There was no known family history of cancer in the first- and second-degree relatives. Patient was the second pregnancy of her mother. Both parents smoked throughout the duration of pregnancy and had no significant exposure to occupational carcinogens, ionizing radiation, alcohol, and medicinal or illegal drugs. During pregnancy, the family lived in a home located ~10 m from a gas station, thus exposing the mother to possible inhalation of gasoline-related fumes (all of the windows of the home were open for 4 hours/day).

Patient 4
A female patient, born at 39 weeks weighing 3260 g. The mother presented with hypertension, which was treated during pregnancy. There was an observation of a CFS in the patient’s forearm and no malformations at birth. There was no family history of cancer observed in the first and second generations. The patient was the second pregnancy of her mother. Both parents were identified as smokers, and there was no consumption of alcohol or exposure to ionizing radiation. The mother performed certain tasks involving exposure to paint while pregnant. In addition, the couple bought a set of new furniture during that time. The father was employed in a family-owned company that manufactures chromium- and nickel-related products and uses gasoline and other petroleum-derived solvents. The father may have introduced these contaminants into the home by returning home wearing contaminated clothing and shoes. All cases are summarized in Table 3.

RESULTS
Statistical Analysis

The population in the Valencia region was 653,158 children <15 years (14.38% of the total population) in 2004 (Table 4). Table 4 illustrates the standardized incidence ratio values for each year of study. The 2004 referral population expected at birth stands out with a value of 16.56. By using SatScan software (http://www.satscan.org) we obtained the Scan statistic.
Sixty-two different chemical substances are known to cause fibrosarcoma in animals under experimental conditions. None of the substances have been tested for intrauterine exposures. Only 3 have been identified to produce fibrosarcoma when inhaled: chrysotile asbestos, ethylene dibromide, and nickel subsulfide.

**Clinical Findings**

Prenatal exposure to gas solvents and its derivatives was present in 3 CSF cases associated with occupational exposure at gas stations and the fourth with indirect exposure at home. Additionally, all cases were exposed to carcinogens from tobacco smoke. In Spain, 50% of children live with a daily smoker. It is therefore difficult to attribute the effect of smoking exposure. It is also difficult to attribute the importance of ionizing radiation on the development of fibrosarcoma, because, during the period of blastogenesis, the cells have a great pluripotency to repair themselves.

**DISCUSSION**

We found a history of exposure to petroleum derivatives in 4 cases of CFS. By using the PEH, a clinical tool to develop a description of suspected cancer cluster, we identified a CFS cluster, although it is not sufficient to meet the Bradford-Hill causal criteria. Previous examples of unusual cancer clusters that led to the identification of a previously unrecognized human carcinogen include scrotal cancer in chimney sweeps exposed to soot, osteosarcoma

With monthly disaggregation we identified a temporal cluster between January and April 2004 (P-value = .05), and with year disaggregation the highest likelihood cluster is the 2004 year with a P value of .276. There is no significant spatial cluster. Finally, we identified a spatiotemporal cluster with 50 municipalities (shading in Fig 1) during January through April 2004 (P-value = .10).

**Review of the Chemical Carcinogenesis Research Information System Database**

Sixty-two different chemical substances are known to cause fibrosarcoma in animals under experimental conditions. None of the substances have been tested for intrauterine exposures. Only 3 have been identified to produce fibrosarcoma when inhaled: chrysotile asbestos, ethylene dibromide, and nickel subsulfide.

SIR, standardized incidence ratio; CI, confidence interval; P0, newborns in Valencia region in millions; P1, population under k year in Valencia region in millions (k = 1, 5, 15); 0, observed cases; S0, expected at birth in Valencia region; S1, expected at k year of age birth in Valencia region (k = 1, 5). The expected cases in Valencia region is obtained under the hypothesis that the global incidence is: expected at birth, 3.7 per million newborns; expected at 1 year of age, 8 per million; expected at 5 years of age, 2 per million.
patients in this cluster were exposed to nickel and dibenz[a,h]anthracene by tobacco smoke and occupational exposure. If leaded gasoline, containing ethylene dibromide, was consistently used in all the gas stations, then Patients 1, 2, and potentially 3 had a plausible mechanism for exposure via inhalation. There may be a more complex pathway for exposure linking known substances and some substances that are yet unidentified and are associated with fibrosarcoma. No exposure to asbestos was noted in these cases.

We believe that the PEH is the best clinical tool to approximate the etiology of rare pediatric diseases. However, it is not sufficient to meet the Bradford-Hill causal criteria. The use of observational information for exposure assessment is a limitation of these cases studies. Although we recognize that the small sample size limits discussion of causality, we propose that the PEH be elaborated in future cases of CFS. To strengthen our case, we propose to include a more in-depth description of maternal occupation during pregnancy so that estimation of exposure is possible. Additional case-control and experimental studies are needed to confirm the current observations. The highest priority should be assigned to examining the chemicals that are already known to be carcinogenic or suspected as carcinogenic to humans.

It is important to use the same questionnaire for both cases and healthy controls and to compare how often these same exposures were mentioned among this control group. Recently, we have adapted the PEH-taking tool for use with our obstetrical population. Green Page reporting on reproductive environmental health constitutes the standard clinical record of pregnant women and includes a series of concise and basic questions to identify environmental exposures.

In conclusion, a detailed and carefully conducted PEH, which includes information about occupational exposure, should be performed for all cases with CFS. Although future studies are needed to systematically investigate the origins of CFS and its underlying mechanisms, this report suggests that increased occupational safety measures should be considered for all pregnant women.
