Translational research often involves tissue sampling and analysis. Blood is by far the most common tissue collected. Due to the many difficulties encountered with blood procurement from children, it is imperative to maximize the quality and stability of the collected samples to optimize research results. Collected blood can remain whole or be fractionated into serum, plasma, or cell concentrates such as red blood cells, leukocytes, or platelets. Serum and plasma can be used for analyte studies, including proteins, lipids, and small molecules, and as a source of cell-free nucleic acids. Cell concentrates are used in functional studies, flow cytometry, culture experiments, or as a source for cellular nucleic acids. Before initiating studies on blood, a thorough evaluation of practices that may influence analyte and/or cellular integrity is required. Thus, it is imperative that child health researchers working with human blood are aware of how experimental results can be altered by blood sampling methods, times to processing, container tubes, presence or absence of additives, shipping and storage variables, and freeze-thaw cycles. The authors of this review, in an effort to encourage and optimize translational research using blood from pediatric patients, outline best practices for blood collection, processing, shipment, and storage. *Pediatrics* 2013;131:754–766
Translational research studies often investigate molecules in human tissues to better understand disease mechanisms or as either a measure of disease outcome or response to therapy. Blood is by far the most common tissue used, but in pediatrics it is often difficult to procure, mandating that best practices are used to yield quality samples for optimal study.1–4 Several factors can affect the quality of the blood samples, including the chosen container tubes, anticoagulants, preservatives and additives, processing times, centrifugation settings, shipping methods, storage variables, and freeze/thaw cycles. Poor attention to details or native practices can negatively influence analyte stability and cellular integrity, potentially distorting the experimental results.5 Furthermore, each biomarker or cell type has its own inherent properties, which may require protocol modifications for quality sample preservation.

In this review, our second in a series on tissue sampling and bio-banking for child health studies,1 we present the pertinent issues that arise from blood collection, processing, shipping, and storage. Our goal is to highlight the different approaches and the best practices to maintain blood samples with the highest integrity. Pediatric-specific issues in translational research, such as study ethics, consent, and sampling volumes, were reviewed by us previously.1

**BLOOD SAMPLE COLLECTION**

Inaccurate experimental results are often secondary to inappropriate specimen collection and handling, or to interference factors.6,7 Laboratory measurements are influenced by hemolysis (high-negative-pressure blood draws or use of tourniquets),7–11 lactescence (nonfasting patients),12 concentration changes (drawing from an infusion line, insufficient filling of vials altering sample/additive ratio),13,14 bacterial contamination (production of ammonia or urea),12 and extravascular interchange.12 Providone-iodine solution used as a skin antiseptic can elevate phosphorus, uric acid, and potassium levels.15 Blood draws from heparinized lines can falsely lower ionized calcium.16

One of the earliest considerations is deciding whether unprocessed whole blood, plasma, or serum is required (Table 1). Unprocessed whole blood requires no further processing once drawn from the patient and can be used for “point of care” testing (POCT).17 POCT offer immediate results that not only can be used for rapid patient diagnostics but also to support research studies. Common POCT includes blood gases, electrolytes, hematocrit, glucose, creatinine, hemoglobin A1C, amylase, cardiac markers, coagulation markers, cholesterol, urinalysis, and streptococcal infection. POCT analyzers can provide precise results that correlate with results from the reference laboratory,18,19 but their accuracy relies on attention to quality control and operator training.

Unprocessed whole blood can be rapidly separated to yield either serum or plasma. Serum samples undergo the process of coagulation, which consumes all available clotting factors from the sample but can also impose artificial effects on the levels of biomarkers. In contrast, plasma is collected into tubes that contain anticoagulants to prevent the clotting of blood, and thereby retains clotting factors in solution. Centrifugation of unprocessed whole blood for plasma also results in isolation of a buffy coat layer, which can be used to produce cell concentrates (ie, leukocytes) for use in a wide array of in vitro studies or as a source of nucleic acids.

Although serum and plasma preparations are often used interchangeably, large differences exist between the proteomes of serum and plasma, making them incomparable to one another.20 Hence, it is critical that either plasma or serum is exclusively chosen for study. Examples of biomarkers altered by blood processing are shown in Table 2.

**BLOOD COLLECTION TUBES**

Evacuated tube systems for blood collection, such as Vacutainer (BD Biosciences, Franklin Lakes, NJ), are available for the isolation of serum, plasma, and buffy coat RNA or DNA. Frequently used blood collection tubes are summarized in Table 3 and should be chosen on the basis of the end-point assay.

**Serum Isolation**

Silicone-coated tubes contain a clot activator and are useful for serum chemistry. Alternatively, serum-separator tubes contain a gel barrier and decrease the incidence of hemolysis, increase sample stability, and facilitate primary tube sampling and storage.21 Disadvantages of gel barrier tubes include instability under extreme temperatures21 and barrier-induced changes in serum drug concentrations.22 The type of serum collection tube that is selected can also have an effect on end-point analysis due to the differences in clotting facilitated by the additives.23 Serum tubes may add unwanted polymeric components to the serum, leading to inaccurate results.24

**Plasma and Buffy Coat Isolation**

Citrate is a common anticoagulant used in plasma collection tubes, resulting in quality DNA and RNA isolation and high yields of lymphocytes that can be isolated for cell culture.25,26 Platelets are stable in citrate,25,27 releasing fewer small peptides into the plasma relative to other anticoagulants.24 Heparin is an alternative anticoagulant used for plasma separation but may alter T-cell proliferation.25,26 Antithrombin III activity, and protein interactions.25,27
Plasma isolated from tubes containing EDTA as an anticoagulant exhibits changes in protein profiles over time as compared with citrate.23

Blood Cell Concentrates

After density gradient centrifugation of whole blood, red blood cells can be isolated from the bottom fraction of the tube, and the buffy coat contains leukocytes and platelets. Further isolation of leukocyte subtypes is usually accomplished with density gradient centrifugation and/or antibody-coated beads.28

Isolated leukocytes provide a means to assess the inflammatory response to disease. The type of anticoagulant, sample collection, and handling and processing techniques, however, can greatly affect the yield, quality, and morphology of isolated leukocytes and can produce sheer stress–induced shape changes, aggregation, and apoptosis. Cell activation, the stimulation of cellular processes initiated as a response to external stimuli, can also be initiated by anticoagulants and enhance phagocytic activity, release lysosomal enzymes, increase cell migration, increase synthesis of plasminogen activator, and increase procoagulatory activity.29

Platelet isolation can result in cell activation, platelet aggregation, and the release of inflammatory mediators.31

DNA in PAXgene tube is stable for up to 5 d at RT and up to 12 mo at −20°C.77

influences cell metabolism and alterations of cell membrane integrity, resulting in release of metabolites and/or degraded products. Immunolabeling and flow cytometry should use whole blood to avoid centrifugation and washing steps, which can lead to artifactual cell activation. Flow cytometry assays should avoid blood taken through intravenous cannulae and should use a direct thrombin inhibitor as an anticoagulant, minimize and standardize time delays between blood collection and processing, and store fixed samples at 4°C before analysis.

Tables 4, 5, and 6 summarize the effects produced by different anticoagulant or processing techniques on a variety of blood cell types.

**ADDITIONAL TUBE ADDITIVES**

Proteins can be degraded or undergo structural modifications due to enzymes naturally present in human blood, including proteases, peptidases, and phosphodiesterases. Protein degradation can be reduced by adding an enzyme inhibitor or inhibitors to the blood and by rapidly separating and freezing plasma. Blood can be collected into calcium chelators, such as citrate, which inhibits calcium-dependent proteases involved in the coagulation cascade. Calcium chelators can be used in combination with enzyme inhibitors. Clotting-related molecules are highly influenced by protease activity in blood or plasma samples, as are samples with activated, disrupted, or lysed neutrophils or mononuclear phagocytes that naturally release enzymes. Tubes containing calcium chelators and enzyme inhibitors are summarized in Table 3.

**DETECTION OF IMMUNOGLOBULINS**

Detection of infectious pathogens is often based on the determination of immunoglobulin antibodies in serum and plasma. Immunoglobulins can be stable at room temperature (RT) for days, but stability increases if serum aliquots are stored in dimethyl sulfoxide at −70°C. The detection of immunoglobulins is altered by blood surfactants that may lead to the loss of antibody from the solid phase, affecting immunoassays during antibody diagnostics. An alternative method for antibody diagnostics is the use of dried blood spots on either filter paper or Guthrie cards. Blood must be dried for several hours at RT and then stored in sealed plastic envelopes at −20°C.

**ISOLATION OF NUCLEIC ACIDS**

Cell-free nucleic acids are present at low levels in the serum and plasma of healthy patients; however, illnesses result in a significant increase in nucleic acid blood levels. Sources of cell-free nucleic acid include the apoptosis/necrosis of normal or cancer cells, or from microorganisms such as bacteria or viruses. Therefore, the study of cell free nucleic acids in serum or plasma offers a valuable research opportunity in specific circumstances. Alternatively, DNA and RNA can be directly isolated from cellular...

fraction, often producing better yield and quality of nucleic acids than unprocessed whole blood.50–54 Potential effects produced by different anticoagulants and processing techniques on DNA and RNA isolation are summarized in Table 7.

DNA Isolation

Proper practice is crucial to ensure quality DNA isolation.55 Commercial kits exist for DNA extraction from serum and plasma, which rely on similar methodologies and produce equivalent yields of DNA.56 The QiAamp Viral Spin kit (Qiagen, Venlo, Netherlands), using silica-based membrane chemistry, is reported to produce high-yield DNA from plasma and serum.57 The ReliaPrep Blood gDNA Miniprep System, based on cellulose-based chemistry, and the Maxwell 16 LEV Blood DNA Kit, based on paramagnetic particle chemistry, provide all-in-one methodologies for DNA purification from either blood or buffy coat (Promega, Fitchburg, WI). The quality and yield of DNA58 can also be obtained inexpensively with traditional phenol/chloroform extraction procedures, but these extractions are time consuming and labor intensive. Tubes containing citrate or EDTA are optimal choices for the isolation of cell-free DNA.57 Alternatively, the PAXgene Blood DNA System is available for collection and stabilization of whole blood for isolation of genomic DNA.

RNA Isolation

It is imperative to prevent degradation of RNA during collection, transport, storage, and processing.59 Commercial kits, using similar methodologies, are available for RNA isolation from blood or cellular fractions with similar efficiency. All kits are intended for easy collection, storage, and transport of blood while maintaining RNA stability, followed by the isolation and purification of RNA. Choices include the QiAamp UltraSens Virus Kit (Qiagen) for isolating mRNA from plasma60 or several alternative kits depending on the type of isolation method, the preparation time, and the type of stabilization reagents (RNAlater; Tempus, PAXgene, EDTA, citrate or heparin tubes; Life Technologies, Carlsbad, CA). BD Vacutainer CPT cell preparation tubes are also available to isolate RNA.

TIMING OF SAMPLE PROCESSING

Blood components are labile in nature, and their integrity requires timely processing. For serum separations, the time allowed for samples to clot is critical, although it varies between samples on the basis of intrinsic clotting factor levels and clinical exposure to anticoagulants. Incubation times longer than required for adequate clotting may result in cell lysis, thereby altering analyte levels.61 Higher molecular weight proteins, such as lipoproteins, are more sensitive to prolonged clotting time, resulting in potential variability.62 Plasma samples do not require time to clot but require rapid processing to limit biomarker alterations.63 Cytokine concentrations in plasma change in <2 hours when maintained at RT.64 In general, nucleic acids should be processed quickly to optimize yield and integrity.58

Ideally, blood should be processed and frozen rapidly after collection.63,65 Placing samples on ice before processing can improve sample preservation; however, samples should still be processed within 30 to 60 minutes to maintain integrity.66 Furthermore, the use of ice or cold packs in the transport of blood from the clinical setting to the laboratory can reduce protein degradation.67 Temperature consistency of samples during processing is imperative to maintain sample quality.68 It is also important to maintain consistent lag times between sample collections and processing.

**STORAGE TEMPERATURE**

Storage temperatures depend on the nature of the analyte that is being preserved. Although DNA isolated from blood samples is stable at 4°C for several weeks, at −20°C for months, and at −80°C for years, RNA degrades quickly at temperatures higher than −80°C. Proteins and other soluble biomarkers have varied stability; immunoglobulins are stable at RT for days, whereas other proteins are exceedingly labile and must be frozen at −80°C. Viable cells can typically survive at RT for ≤48 hours, but they must be eventually cultured at physiologic temperatures or frozen in liquid nitrogen with a cryoprotective agent for long-term preservation.

In general, −80°C is usually sufficient to preserve a broad range of molecules. Protein profiling is preserved for ≥4 years of storage at −70°C. Nonetheless, the long-term stability of many molecules is poorly understood, and long-term storage of samples should be limited to <4 years from sample procurement.

**FREEZE-THAW OF SAMPLES**

Although frozen samples are stable for long-term storage, they are especially vulnerable to freeze-thaw cycles. Freeze-thawing results in the formation of ice crystals, which can cause significant destruction to biological molecules. A single freeze-thaw at −70°C decreases the yield of DNA by 25%, and multiple freeze-thaw cycles can influence many other molecules. Freeze-thaw damage is limited by aliquoting samples into small volumes that are sufficient for a single experimental, and then flash-freezing samples with either liquid nitrogen or by cooling ethanol on dry ice for tube submersion.

**SHIPMENT**

Blood specimens, with or without infectious agents, are considered dangerous goods and must be properly classified, identified, packed, labeled, and handled for shipping. Various agencies have published rules and regulations regarding the transportation of medical specimens on the basis of the associated risks and safety standards, and they also provide training and expert advice on dangerous goods transportation. International Air Transport Association (IATA) guidelines for transport of dangerous goods as well as local laboratory protocols must be followed.

Specimens must be kept within a specific temperature range during shipment to protect sample integrity. Temperature maintenance and packaging depend on the nature of the sample and the proposed analysis. Samples can be shipped at RT (20–30°C), refrigerated (2–8°C), or frozen (−20°C, −70°C, −150°C). Shipping boxes and packs to maintain specific temperatures, in addition to absorbent strips, bubble wrap, and polypropylene secondary-pressure vessels with O-rings for leak-proof packaging, are available. Samples that should be maintained below −70°C require dry
ice in the shipping box, whereas a liquid nitrogen dry shipper must be used for samples shipped at $-150^\circ\text{C}$.

Packing of frozen specimens with dry ice requires "UN" dry ice labeling on the box, including the name and addresses of shipper and consignee, and the weight of the dry ice must be marked near the class 9 diamond-shaped hazard label.

Specimens are designated category "A" if they are blood samples or cultures known to contain certain infectious agents or category "B" if they are blood specimens typical of clinical diagnostic tests. Specific leak-proof containers for specimens classified as A or B are available commercially.

Category A specimens must be shipped in a certified container according to IATA regulations. Several commercial laboratories offer a variety of infectious certified containers for frozen, refrigerated, or ambient specimens that include secondary and outer packages and in most cases contain the appropriate hazard labels. Category A specimens are assigned to UN2814-Infectious Substance, affecting humans. The assignment to UN2814 is based on the medical history of the patient or by his or her symptoms. If it is not clear whether a pathogen falls within this category, it must be transported labeled as a Category A Infectious Substance. To help with the assignment, the IATA has created a table with examples of different pathogens that meet the criteria of category A.

be capable of passing the IATA drop-test from a height of not less than 1.2 m. For liquids, absorbent material (e.g., cellulose wadding, cotton balls, superabsorbent packets, and/or paper towels) in sufficient quantity to absorb the entire contents in the package must be placed between the primary receptacle or receptacles and the secondary packaging. Category B specimens are assigned to UN3373 with a diamond-shaped hazard label, a proper shipping name of biological substance “Category B,” and Packing Instruction 650.

Specimens derived from patients that are unlikely to cause disease or do not contain infectious substances are not subject to regulations unless they meet a criterion of inclusion, and they must be in a triple package according to Packing Instruction 650 and marked with the words “Exempt human specimens.”

### CONCLUSIONS

This review summarizes pertinent issues in the collection, processing, shipping, and storage of blood samples for use in child health research studies. Importantly, there is no single ideal method for the preservation and storage of all types of samples. It is advisable to consider each analyte of interest unique and to investigate its stability and integrity before the procurement of a large number of samples. A pilot study in which control blood samples are processed and markers of interest are investigated is ideal, ensuring that the standard operating protocols are sufficient for the preservation of samples and limiting the potential for quality control issues.

### ACKNOWLEDGMENT

We thank Mr David Carter of the London Regional Genomics Centre for critical review.
