abstract

BACKGROUND AND OBJECTIVE: Heated, humidified high-flow nasal cannula (HHHFNC) is commonly used as a noninvasive mode of respiratory support in the NICU. The safety and efficacy of HHHFNC have not been compared with other modes of noninvasive support in large randomized trials. The objective was to assess the efficacy and safety of HHHFNC compared with nasal continuous positive airway pressure (nCPAP) for noninvasive respiratory support in the NICU.

METHODS: Randomized, controlled, unblinded noncrossover trial in 432 infants ranging from 28 to 42 weeks’ gestational age with planned nCPAP support, as either primary therapy or postextubation. The primary outcome was defined as a need for intubation within 72 hours of applied noninvasive therapy.

RESULTS: There was no difference in early failure for HHHFNC (23/212 [10.8%]) versus nCPAP (18/220 [8.2%]; P = .344), subsequent need for any intubation (32/212 [15.1%] vs 25/220 [11.4%]; P = .252), or in any of several adverse outcomes analyzed, including air leak. HHHFNC infants remained on the study mode significantly longer than nCPAP infants (median: 4 vs 2 days, respectively; P < .01), but there were no differences between study groups for days on supplemental oxygen (median: 10 vs 8 days), bronchopulmonary dysplasia (20% vs 16%), or discharge from the hospital on oxygen (19% vs 18%).

CONCLUSIONS: Among infants ≥28 weeks’ gestational age, HHHFNC appears to have similar efficacy and safety to nCPAP when applied immediately postextubation or early as initial noninvasive support for respiratory dysfunction. Pediatrics 2013;131:e1482–e1490

WHAT’S KNOWN ON THIS SUBJECT: Heated, humidified high-flow nasal cannula (HHHFNC) is a noninvasive mode of respiratory support that is commonly used in the majority of US NICUs. No large randomized trial has evaluated safety or efficacy of HHHFNC.

WHAT THIS STUDY ADDS: This large randomized controlled trial suggests that HHHFNC is as effective as nCPAP for noninvasive respiratory support and can be safely applied to a wide range of neonates.

Respiratory failure remains a common problem in the NICU. Concerns with ventilator-induced lung injury have led to a concerted effort in many NICUs to avoid prolonged ventilator support through early application of noninvasive modes of respiratory support, most often nasal continuous positive airway pressure (nCPAP). CPAP systems are not always easily applied or well tolerated in the neonatal population. Difficulties with the application of nCPAP include complicated fixation techniques, positional problems, nasal trauma, and apparent agitation. The use of increased nasal cannula (NC) flow to deliver positive airway pressure was initially described by Locke et al in 1991 in 13 preterm infants. They reported the potential to deliver positive pressure with NC flows up to 2 L per minute (lpm), given a large NC diameter (3 mm). They cautioned about indiscriminate use of higher flow rates via NC due to potential for unregulated pressure delivery. Ten years later Sreenan et al used the term “high-flow nasal cannula” in reporting that NC flows up to 2.5 lpm could be as effective as nCPAP for treating apnea of prematurity, and that delivered pressure via NC flow could be regulated by using esophageal pressure measurements. Standard NC systems routinely use inadequately warmed and humidified gas, limiting use of higher flow rates secondary to the risk of mucosal injury and nosocomial infection. To circumvent these concerns, heated, humidified high-flow nasal cannula (HHHFNC) systems were developed as possible alternatives to nCPAP for noninvasive respiratory support of neonates. Over the past decade, HHHFNC use has become widespread across academic and nonacademic NICUs in the United States, as well as globally (R.H. Clark, personal communication, 2012; refs 10 and 11). The introduction of HHHFNC into clinical practice has not been accompanied by apparent changes in neonatal outcome, but this has not been systematically studied in a randomized controlled approach. Early retrospective and observational studies suggested that HHHFNC can be applied safely and effectively as noninvasive respiratory management of premature infants with respiratory dysfunction. Despite increasing popularity, caution has been voiced due to concerns regarding both efficacy and safety of HHHFNC in comparison with other noninvasive modes. The purpose of this randomized controlled trial was to test the null hypothesis that there is no difference between HHHFNC and nCPAP in preventing extubation failure when applied as noninvasive respiratory support modes for neonates with respiratory dysfunction.

METHODS

This was a prospective, randomized, unblinded controlled trial that was approved by the institutional review board of the University of Utah and by the institutional review board at each participating site (University Hospital, Primary Children’s Medical Center, and Intermountain Medical Center, Salt Lake City, UT, Utah Valley Regional Medical Center, Provo, UT, McKay Dee Regional Medical Center, Ogden, UT, Hebei Provincial Children’s Hospital, Shijiazhuang, China; Wilford Hall Medical Center, Lackland Air Force Base, TX; University of Pennsylvania Hospital, Philadelphia, PA). Informed parental consent was obtained before any study involvement. This study was registered at clinicaltrials.gov (NCT00609882).

Study Population

Infants were eligible for study inclusion if they met the following criteria: (1) birth weight ≥1000 g and gestational age ≥28 weeks and (2) at the time of randomization there was an intention to manage the infant with either noninvasive (no endotracheal tube) respiratory support from birth initiated in the first 24 hours of life or noninvasive respiratory support at any age after a period of mechanical ventilation with an endotracheal tube. Infants were excluded from study participation for the following reasons: (1) birth weight <1000 g, (2) gestational age <28 weeks, (3) presence of active air leak syndrome, (4) concurrent participation in a study that prohibited HHHFNC, (5) abnormalities of upper and lower airways (Pierre-Robin, Treacher-Collins, Goldenhar, choanal atresia, cleft lip/palate), or (6) serious abdominal, cardiac, or respiratory malformations including tracheal esophageal fistula, intestinal atresia, omphalocele, gastrochisis, or diaphragmatic hernia.

Randomization

Infants were randomly assigned at each study site via opaque sealed envelopes in blocks of 10 by study site by using random-number generation. Randomization was stratified by the following: birth weight 1000 to 1999 g or ≥2000 g and age at randomization of ≤7 days or >7 days of age.

Study Devices

No specific device for nCPAP or HHHFNC has shown superiority over another; therefore, we did not dictate a particular approach for nCPAP or HHHFNC. nCPAP was provided by various interfaces including bubble, Infant Flow nCPAP System (in CPAP mode only, not for SiPAP; CareFusion, Yorba Linda, CA), and ventilator. Devices used for HHHFNC included Comfort Flo (Hudson RCI, Research Triangle, NC), Fisher and Paykel Healthcare (Irvine, CA), and Vapotherm (Stevensville, MD). Vapotherm devices (6 devices, 2000i) were provided on loan for use at 3 of the study sites.
Study Procedure

Management of HHHFNC

Nasal cannulas were applied per manufacturer suggestions with recommendations that the prong outer diameter occupy ~50% of the nares internal diameter. Free egress of flow around the cannula was routinely auscultated by respiratory therapy and nursing staff. Fraction of inspired oxygen (FIO2) was initiated at the same value if the infant was on another mode of noninvasive support, but 5% to 10% higher if the infant was being extubated. Initial flow rate for HHHFNC (in lpm) was determined by the current infant weight as follows: (1) 1000 to 1999 g = 3 lpm, (2) 2000 to 2999 g = 4 lpm, and (3) ≥3000 g = 5 lpm. Flow rate could be increased within each weight category by a maximum of 3 lpm above the starting flow rate. We recommended increasing the flow rate in 1-lpm increments if (1) FIO2 increased by >10% above the starting FIO2, (2) pCO2 increased by >10 mm Hg above the baseline value, (3) increased distress or retractions were noted, or (4) decreased lung expansion was noted on chest radiograph. We recommended decreasing the flow rate by 0.5- to 1.0-lpm increments if all of the following were sustained for at least a 4-hour period: (1) FIO2 <30% and oxygen saturation within ordered parameters, (2) pO2 was maintained within ordered parameters, (3) no signs of significant distress were noted, and (4) lung expansion was deemed adequate, if chest radiograph was obtained (chest radiographs and blood gas measurements were obtained only as clinically indicated per the attending clinician).

Management of nCPAP

The recommended starting pressure for nCPAP was 5 to 6 cm H2O or a value equivalent to the positive end-expiratory pressure level on ventilator support. nCPAP pressure could be increased to a maximum of 8 cm H2O on the basis of the same criteria used for escalating the HHHFNC flow rate. nCPAP support was weaned by using the same weaning criteria as for weaning from HHHFNC.

Discontinuation of Study Support

Transition to standard NC or oxygen hood therapy was recommended when the HHHFNC flow rate was weaned to <2 lpm or when nCPAP was weaned to 4 to 5 cm H2O and the infant remained stable based on the above criteria, including an FIO2 <30%.

Recommended Blood Gas and Oxygen Saturation Values

Oxygenation and ventilation goals were established by each site on the basis of internal protocols. Recommended saturation goals ranged from 85% to 98% depending on gestational age, retinopathy of prematurity risk, and presence of pulmonary hypertension. Recommended values for pO2 were 40 to 65 mm Hg for arterial blood gases and 45 to 0 mm Hg for capillary blood gases.

Primary Outcome

The primary outcome was defined by failure of the study support mode as determined by intubation within the first 72 hours of study support. Similar guidelines for intubation were used at each study site (Table 1). Crossover between HHHFNC and nCPAP was permitted for the first 72 hours of study support. Infants “failing” either during intervention during the first 72 hours of support were required to be intubated. After the initial 72 hours of study support, or after failure requiring intubation, any mode of noninvasive respiratory support was allowed at the discretion of attending provider.

Secondary Outcomes

Data were collected until hospital discharge on all enrolled infants. Numerous secondary outcomes were established a priori including the following: (1) total ventilator days, days of noninvasive support (nCPAP and/or HHHFNC), and oxygen use up to the time of discharge; (2) need for delayed intubation (beyond 72 hours of study support); (3) frequency of adverse events including significant apnea, pulmonary air leaks, feeding intolerance, abdominal distention, necrotizing enterocolitis, intestinal perforation, and late-onset nosocomial infection; (4) assessment of nasal mucosal injury and respiratory effort determined at specified intervals by using scoring systems previously reported by Woodhead et al; (5) overall infant comfort (assessed by a bedside nurse and respiratory therapist at 24-hour intervals (by using a 3-point Likert scale); (6) the incidence of BPD (based on an oxygen reduction test)18; and (7) discharge from the hospital on oxygen. We also evaluated the impact of HHHFNC and nCPAP on time to establish full oral enteral feedings (≥120 mL/kg per day).

PPV, positive pressure ventilation; SpO2, pulse oxygen saturation.
of infants was determined to be ~15% on the basis of a 2-year (2005–2006) retrospective review of NICU admissions at the University of Utah. We determined a 50% reduction in risk to be clinically significant. To reliably detect this difference between the 2 study groups with an \( \alpha \) (type I error) of 0.05 (2-tailed) and a power of 80% (\( \beta = .20 \)), we determined that a sample size of 190 infants per group was needed. We assumed a 10% loss from withdrawal or late exclusion and thus sought to enroll 210 infants in each study group.

The primary outcome was analyzed by \( \chi^2 \) as an intention-to-treat analysis. \( \chi^2 \) or Fisher’s exact test were used for all other categorical comparisons. Student’s \( t \) test was used for analysis of normally distributed continuous data. Mann-Whitney \( U \) test was applied for ordinal data or continuous data that were not normally distributed. Two-sided \( P \) values <0.05 were considered statistically significant, and no adjustments were made for multiple comparisons. Statistical analysis was performed by using SPSS (version 19; IBM, Armonk, NY).

Before study initiation we planned a single interim analysis to be performed after 50% accrual of study enrollment. Analysis was conducted by an external data safety monitoring committee by using predefined criteria for recommending either continuation or cessation of the trial.

**RESULTS**

A total of 432 infants from 8 level III NICUs were enrolled between December 2007 and April 2012. As shown in Fig 1, 220 infants were randomly assigned to nCPAP and 212 to HHHFNC. Outcomes were available for all study infants, including 1 infant in the nCPAP group whose parents withdrew consent for study participation after early nCPAP failure but allowed continued data collection until discharge from the hospital. There were 5 deaths: 1 in the HHHFNC group (38 weeks, died at 48 days with severe pulmonary hypertension) and 4 in the nCPAP group (29 weeks at 12 days from acute encephalopathy, 31 weeks at 4 days from acute herpes simplex encephalitis, 34 weeks at 25 days from severe pulmonary hypertension, and 36 weeks at 100 days from severe pulmonary hypertension).

Demographic characteristics were similar between the 2 groups at time of randomization (Table 2). More than 90% of the infants were <7 days of age at initial randomization with respiratory distress syndrome being the most common diagnosis.

There was no significant difference between nCPAP and HHHFNC in the primary outcome rate for failure of study mode and intubation within the first 72 hours of therapy (Table 3). Subgroup comparisons, including gestational age <32 weeks, mechanical ventilation at time of randomization, and study entry before 7 days of age, also revealed no differences in early respiratory failure by study mode. Adjustment for gestation, birth weight, ventilator support, surfactant therapy, and primary diagnosis did not alter the failure to identify a significant difference between the 2 study modes for early intubation (odds ratio: 1.67; 95% confidence interval: 0.79–3.52). All but 1 of 41 infants with early failure were intubated within 36 hours of study entry (median: 11 hours [25%] to 4–20 hours [75%]). Reasons for early failure and intubation were similar between both study modes and were as follows: increasing respiratory distress nCPAP (\( n = 15 \) [83%]) and HHHFNC (\( n = 19 \) [83%]; \( P = .951 \)), increased FIO2 nCPAP (\( n = 9 \) [50%]) and HHHFNC (\( n = 9 \) [39%]; \( P = .539 \)), and severe apnea nCPAP (\( n = 2 \) [11%]) and HHHFNC (\( n = 5 \) [22%]; \( P = .438 \) (note: total numbers exceeded 41 because 18 infants had >1 reason cited for early failure and intubation). There was also no difference between centers for rates of early failure.

Although we found no difference in ventilator days, infants managed with nCPAP had fewer days of any positive pressure support (ventilator, nCPAP, or HHHFNC) as well as shorter duration of study mode support than infants managed by HHHFNC (median: 2 fewer days; Table 4 and Fig 2). By 7 days after study entry significantly more infants remained on HHHFNC (median: 2 fewer days; Table 4 and Fig 2). By 7 days after study entry significantly more infants remained on HHHFNC (median: 2 fewer days) compared with nCPAP (median: 20 [9%]; \( P < .001 \)). Despite the longer time on any positive pressure support for HHHFNC study infants, there was no difference in time to wean to room air. Diagnosis

![Study flowchart for infants by randomization mode.](image-url)
of bronchopulmonary dysplasia (BPD) at 36 weeks’ gestational age for infants born at <32 weeks’ gestation was similar between study groups, as was the proportion of infants discharged from the hospital on oxygen (Table 4).

After study entry, several potential adverse outcomes were closely monitored. As shown in Table 5, the overall adverse event rate was similar between infants randomly assigned to nCPAP compared with HHHFNC. Importantly, the rate of any form of air leak occurring on study mode support was quite low and not different between groups. There were also no differences in the occurrence of increased apnea or sepsis, frequency of delayed intubation, or time to full oral feedings between study groups. The only difference in measured adverse outcomes was a small but statistically significant higher rate for any nasal trauma during nCPAP support (Table 5).

We compared infants successfully managed by either study mode with those with early study failure to determine if there were identifiable characteristics that might help to predict early failure. We did not find any differences in prestudy characteristics (Table 6). Specifically, gestational age, birth weight, surfactant therapy, prestudy respiratory support mode, respiratory support pressure, and FiO2 were similar for infants experiencing early failure compared with those successfully managed by either nCPAP or HHHFNC.

Rates for early failure were not significantly different between devices ($P = .521$): Fisher and Paykel (16 of 143; 11%), Vapotherm (4 of 52; 8%), and Hudson Comfort-Flo (3 of 17; 18%). Likert scale assessments from the bedside nurse and respiratory therapist related to ease of care and patient comfort revealed no differences between the 2 study modes.

**DISCUSSION**

In this multicenter randomized trial involving neonates ≥28 weeks’ gestational age undergoing planned noninvasive respiratory support, we found no significant difference between HHHFNC and nCPAP with regard to the primary outcome of intubation within the initial 72 hours of support. In addition, we found no differences between infants randomly assigned to nCPAP compared with HHHFNC for several respiratory outcomes, including duration of oxygen supplementation, diagnosis of BPD, or discharge from the hospital on oxygen. Despite concerns over unregulated/unmonitored pressure delivery during HHHFNC support, we found no differences in the occurrence rate for any form of air...
leak. The outcome results from this relatively large randomized trial indicate that the use of HHHFNC, as described in this report, appears to be as effective and as safe as nCPAP in this population of infants.

The actual approach to “high-flow” nasal cannula must be carefully considered in evaluating all studies. Some investigators have described “high-flow” in the presence of flow limited to 1 to 2 lpm and in the absence of a well-heated, humidified gas source for flow. Flow limitation has been based on earlier studies from Locke et al5 and Sreenan et al6 suggesting the potential for high, unregulated positive airway pressure. Over the past decade, systems have been designed to allow much higher flow rates (2–8 lpm for neonates and up to 50 lpm in adults) accompanied by optimal heating (37°C) and humidification (100%) of the delivered gas. We, and others, have defined this system of NC therapy as heated, humidified high-flow nasal cannula or HHHFNC.19 Recent studies have reported much lower airway pressures using HHHFNC, both indirectly via pharyngeal or esophageal pressure measurement and, in an animal model of neonatal respiratory distress, directly via intratracheal pressure monitor.20–23 The importance of the NC interface in the potential delivery of airway pressure should not be minimized. In recent neonatal studies, external NC diameters were typically limited to <3 mm. This size appears to be a critical dimension for neonatal HHHFNC, because Locke et al6 demonstrated that high airway pressures were measurable with a cannula diameter of 3 mm but not when the cannula was 2 mm in diameter. All infants in our study were managed with NC having an external diameter of <3 mm, with 95% measuring <2.0 mm.

Several retrospective and observational studies have been published suggesting that HHHFNC may be effective and safe in managing preterm infants with respiratory dysfunction.8,12–14 It is important to differentiate findings from these reports from those of other investigations in which high-flow nasal cannula has been applied with the use of inadequately heated/humidified gas at significantly lower flow rates. Abdel-Hady et al24 reported that weaning from nCPAP to high-flow NC limited to 2 lpm was associated with longer duration of oxygen and respiratory support compared with infants maintained on nCPAP until weaned directly to room air. In their study, not only was NC flow rate limited but the gas conditioning may have been inadequate. Campbell et al25 reported in 40 infants that “HF-CPAP” [high-flow CPAP], administered via standard NC, was less effective at preventing reintubation than nCPAP. There were limitations in NC flow rate (range: 1.4–1.7 lpm) and gas conditioning similar to those in the Abdel-Hady et al study, and “HF-CPAP”

pressures were assumed rather than measured. The importance of adequate
gas conditioning to upper and lower
airway function is well described and
includes reduced metabolic work,
maintained ciliary function, prevention
of airway desiccation and squamous
epithelial cell injury, reduced inspira-
tory work of breathing, and im-
proved lung mechanics.\textsuperscript{7,19,26}

With the inclusion of HHHFNC as a mode of “positive pressure” support, we
found a slight but significant increase in
days of any positive pressure sup-
port among infants randomly assigned
to HHHFNC. This increase was associ-
ated with an extended use of HHHFNC in
that study group. The reasons for this
are unclear. We were not able to iden-
tify differences between groups in
bedside nurse or respiratory therapist
assessment of patient comfort, device
humidification, or ease of use. This
result is in contrast to recent pediatric
and adult studies reporting improved
patient comfort with HHHFNC com-
pared with nCPAP.\textsuperscript{29,30} Although we did
not find a measureable difference in
nursing/respiratory therapist assess-
ment, a potential “preference” by care
providers may still have existed and
contributed to the median 2-day in-
creased time infants in the HHHFNC
study group were managed on the
study mode. Despite the difference in
duration of positive pressure support
we did not observe sustained long-
term effects between infants man-
aged on nCPAP compared with HHHFNC
based on similar duration of oxygen
support, BPD rates among preterm
infants, length of hospitalization, and
home oxygen use.

Similar to the study by Miller and
Dowd\textsuperscript{13} we did not identify any differ-
ence in preventing early intubation
between the different HHHFNC devices
used. However, numbers were small
and the power to detect any difference
was limited.

There are several limitations to our
study. First, the study groups could not be
blinded. Given that more infants in
the nCPAP group were switched to
HHHFNC after the initial 72-hour study
window, it is possible that HHHFNC may
have been preferred by the bedside
providers. In addition, in some centers it
became more difficult over time to get
permission to approach parents about
study participation due to clinical
provider preference for 1 mode of
support over the other (more often
HHHFNC than nCPAP); given limited
study resources we were unable to track
this additional source of potential study bias. Thus, some degree of bias
cannot be completely ruled out. We did
not measure pressure at any point in
the airway. Other studies have mea-
sured these pressures in similar or
smaller infant populations by using
flow rates comparable to those we
used.\textsuperscript{21–23} Given the large number
of infants enrolled and the multiple cen-
ters participating, we determined that
measurement efforts would be prob-
lematic. We did restrict enrollment to
infants $\geqslant$28 weeks’ gestational age.
This restriction was due to the pres-
ence of competing studies initiated at
several centers before the HHHFNC/
nCPAP trial that involved infants <28
weeks and/or $<1000$ g, and in which
the use of HHHFNC was specifically
proscribed. Other large randomized
trials will be needed to investigate the
efficacy and safety of HHHFNC use in
this population. Because the majority
of infants had a primary diagnosis of
respiratory distress syndrome, we
cannot necessarily infer that the ap-
parent effectiveness and safety of
HHHFNC compared with nCPAP will be
found for all types of neonatal res-
piratory diseases. Finally, we did not
limit participation to only those infants
being extubated from mechanical ven-
tilator support. Approximately one-
third of the study population was ran-
domly assigned before any mechanical
ventilation, and the majority were al-
ready on early CPAP support. Given the
significant trend over the past decade
to use noninvasive modes of respira-
tory support to prevent intubation
and mechanical ventilation, we decided
that it would be important to include
any infants deemed candidates for
nCPAP as appropriate study partic-
ipants. We found similar early failure
rates regardless of prestudy respira-
tory support mode, suggesting this
was a reasonable assumption.

By the study design, we planned to
achieve 80% power to detect a 50% risk
reduction in early intubation between
nCPAP and HHHFNC by assuming a
pooled outcome rate of 15% and 420
subjects. The actual pooled primary
outcome rate observed was 9.5% in the
study based on a total of 432 study

patients. On the basis of the actual $n$ and observed outcome rates, we obtained 80% power to detect a 60% relative risk reduction. Assuming the observed rates for early intubation remain the same (8.2% vs 10.8%), a total of 3000 infants would need to be randomly assigned to the 2 study groups to demonstrate statistical significance with a power of 80% and a $P$ value $<0.05$.

**CONCLUSIONS**

For the conditions represented in this population of infants $\geq$28 weeks gestational age, HHHFNC appears to have similar clinical efficacy and safety to nCPAP as a mode of noninvasive respiratory support. This finding was evident whether HHHFNC was used as the initial mode of support or when primarily applied at the time of extubation. Additional large randomized trials are needed to evaluate the use of HHHFNC among smaller preterm infants as well as to compare different devices for and approaches to administering HHHFNC.

**ACKNOWLEDGMENTS**

The following investigators, in addition to those listed as authors, participated in this study: C. Liu, MD, Y. Jiang, MD (Hebei Children's Hospital); J. Burnett, RN, K. Weaver-Lewis, RN (Intermountain Medical Center); R. Christensen, MD, Daniel Woodhead, RRT (McKay-Dee Hospital); C. Spencer, RN (Primary Children's Medical Center); T. Mancini, RN, P. Hoffman-Williamson III, BA (Pennsylvania Hospital); and K. Osborne, RN, K. Bird, RN, K. Zanetti, RN (University of Utah).

The members of the Data and Safety Monitoring Committee were as follows: R. Roberts, McMaster University, Hamilton, Canada; Peter Grubb, Vanderbilt University, Nashville, TN; and Reese Clark, Pediatric-Obstetric Center for Research and Education, Sunrise, FL.

We are indebted to the infants and their parents who agreed to take part in this study and to the NICU nursing and respiratory therapy staff of each study center for their dedicated care of the infants and support of this study. Since the time of this study, Wilford Hall Medical Center has discontinued inpatient services and become Wilford Hall Ambulatory Surgical Center; the NICU has relocated to the San Antonio Military Medical Center, Fort Sam, Houston, TX.
