Medication Adherence Among Pediatric Patients With Sickle Cell Disease: A Systematic Review

OBJECTIVES: Describe rates of adherence for sickle cell disease (SCD) medications, identify patient and medication characteristics associated with nonadherence, and determine the effect of nonadherence and moderate adherence (defined as taking 60%–80% of doses) on clinical outcomes.

METHODS: In February 2012 we systematically searched 6 databases for peer-reviewed articles published after 1940. We identified articles evaluating medication adherence among patients <25 years old with SCD. Two authors reviewed each article to determine whether it should be included. Two authors extracted data, including medication studied, adherence measures used, rates of adherence, and barriers to adherence.

RESULTS: Of 24 articles in the final review, 23 focused on 1 medication type: antibiotic prophylaxis (13 articles), iron chelation (5 articles), or hydroxyurea (5 articles). Adherence rates ranged from 16% to 89%; most reported moderate adherence. Medication factors contributed to adherence. For example, prophylactic antibiotic adherence was better with intramuscular than oral administration. Barriers included fear of side effects, incorrect dosing, and forgetting. Nonadherence was associated with more vaso-occlusive crises and hospitalizations. The limited data available on moderate adherence to iron chelation and hydroxyurea indicates some clinical benefit.

CONCLUSIONS: Moderate adherence is typical among pediatric patients with SCD. Multicomponent interventions are needed to optimally deliver life-changing medications to these children and should include routine monitoring of adherence, support to prevent mistakes, and education to improve understanding of medication risks and benefits. Pediatrics 2014;134:1175–1183
BACKGROUND

Sickle cell disease (SCD) is a genetic disorder affecting approximately 100 000 people in the United States.1 SCD is associated with high morbidity and mortality rates. In the past decade, several new medications have become available that have the potential to prolong the duration and improve the quality of life for pediatric patients with SCD.2 Medications shown to be efficacious in research studies may be less effective in clinical practice because of nonadherence.3,4 Adherence has been defined as “the extent to which a patient is taking his medication as prescribed by his healthcare providers.”4 Poor adherence reduces the effectiveness of medications, places patients at risk for serious complications, and significantly increases health care costs.3,4 For example, nonadherence to antibiotic prophylaxis may leave young children with SCD susceptible to overwhelming sepsis and death.5 Nonadherence is estimated to account for $100 to $300 billion in annual US health care costs.6,7 Clinicians report that nonadherence to medications and to monitoring are barriers to treatment in SCD.8 When asked about factors important to adherence to prophylaxis in patients with SCD, clinicians perceptions of important factors did not always agree with factors that actually affect adherence; for example, only 8% included patient fear of side effects and only 20% patient doubts about medication effectiveness.9

Although providers recognize that nonadherence to SCD medications poses a significant barrier to effective disease management, they may have difficulty identifying which patients in their practice exhibit nonadherent behaviors. Approaches to assessing and monitoring adherence by most health care teams may not reliably identify nonadherent patients.10 Compared with more objective methods of estimating adherence (eg, pill count, prescription refill count, serum or urine drug levels), report measures tend to overestimate adherence.4 In addition, adherence to sickle cell medications may vary in other factors such as frequency of use and monitoring required, as seen in other conditions.5,11 Poor adherence to medications in other chronic illnesses has been related to medication, patient, and family characteristics.4,12 To improve clinicians’ understanding of medication adherence in pediatric patients with SCD, we conducted a systematic review of the literature. Among pediatric patients with SCD, our aims were to describe rates of adherence for different SCD medication types, identify patient and medication characteristics associated with nonadherence, and describe the effect of nonadherence and moderate adherence (defined as 60%–80% of doses taken) on clinical outcomes.

METHODS

Article Retrieval

We performed a systematic review of PubMed, Cochrane, Embase, Scopus, Web of Science, and the World Health Organization Global Health Library in February 2012 for publications after 1940. Search terms included medication names (eg, hydroxyurea or penicillin prophylaxis), disease names (eg, sickle cell anemia or hemoglobin SS), and adherence terms (eg, patient adherence or medication noncompliance) (see the Appendix). The search was performed by a professional librarian (K.L.) who did not restrict the search in any way; the results of this search were screened by clinician reviewers for relevance to study objectives. In addition, we performed an ad hoc search of bibliographies of articles selected for review to identify additional references not identified in our primary search.

Study Selection

Studies were included if they addressed medication adherence, included patients with SCD, were in English, included pediatric patients <25 years old, and were primary research studies (ie, not

FIGURE 1
Abstracts identified by search strategy and included in final literature review.
a literature review or editorial) (Fig 1). Each abstract was reviewed by two authors (D.G.B., S.L.C., P.K., K.E.W.), who made decisions about whether the full-text article should be reviewed. If ≥1 author felt the article should be reviewed, it was. Each full article was then independently reviewed by 2 authors who made judgments about whether the article should be included in the final review using a standard data form. Reasons for exclusion were recorded. Disagreements were resolved through discussion.

Data Extraction
We adapted a data collection method from those used in our previous research to capture information about study design, medication type, population age and diagnoses, measures of adherence, adherence rates, patient and medication diagnoses, measures of adherence, and clinical effects of nonadherence or moderate adherence.13–15 As in previous studies, information from each article was entered independently by 2 authors (K.E.W. and C.M.) to minimize bias in data extraction.16 Differences in extraction were reconciled through rereview of the article.

We classified articles based on type of medication studied and, within medications, by the method used to measure adherence, because adherence rates vary depending on the method used.4 Articles included in the review described a range of methods for measuring adherence. These included by report (by parent or adolescent, by clinician, or Morisky scale17–19), direct measurements of unconsumed medication (pill count or measurement of remaining volume for liquid medications), medication monitoring devices (eg, Medication Event Monitoring System [MEMS] caps recording frequency and timing of bottle opening), pharmacy claim data (eg, medication possession ratio [MPR]: days supplied divided by the number of days of observation from the first dispensed dose to the end of a specified follow-up period),20 and drug level (eg, urinary assay).21–25 We assessed reliability of the results for the articles using the Newcastle–Ottawa Quality Assessment Scale; this checklist, which has been used in several studies, is designed to assess the quality of observational studies used in systematic reviews.22–25 Of the 8 domains in the checklist for cohort studies, 4 were relevant to the studies. One author rated all included studies on these 4 items: representativeness of the population, assessment of adherence, adequacy of follow-up, and length of follow-up. For young pediatric patients, studies used parents and other primary caregivers as reporters of adherence. Throughout this article we refer to the primary caregiver for the child as “parent.” From each article, we identified risk and protective factors for adherence along each step in the medication use pathway (prescribing, dispensing, administering, monitoring).26 Finally, we defined levels of moderate adherence as taking 60% to 80% of doses.

RESULTS
Our initial search identified 299 abstracts; an additional 15 articles were identified from cited references (Fig 1). Ninety-one articles were identified for full review. Of these, 24 met all inclusion criteria; data were abstracted and tabulated for this review.

Studies enrolled 10 to 519 subjects, but only 5 studies (21%) had more than 100 patients. Seven studies were multisite; 4 were drug trials, in which analysis of medication adherence was a secondary aim. Studies sometimes were missing adherence data for many subjects. For example, 1 study evaluated antibiotic adherence in 50 children using parent report and urine samples, but only 23 urine samples were obtained.27 There were 14 prospective studies; 8 evaluated the clinical impact of nonadherence, and 4 provided information about the effect of moderate adherence on clinical outcomes. Regarding risk for bias in the included studies, according to the Newcastle–Ottawa Quality Assessment Scale, all studies had adequate length of follow-up period, and 92% had adequate assessment of adherence.22,23 Seventy-five percent had adequate representativeness of the sample population; the remaining 25% failed to state how they derived the study cohort. Eighty-eight percent of studies had adequate follow-up information; the 3 studies that did not had missing adherence information on a large portion of the study cohort.

Adherence Rates
Overall rates of adherence were higher for reported measures (48%–89% adherent) than for objective measures such as urinary assays (40%–56% adherent) or pharmacy refill data (12%–60% adherent) (Table 1). Only 1 article compared adherence to different types of medications for SCD and found similar rates of adherence for hydroxyurea (mean MPR 60%), folic acid (mean MPR 61%), and penicillin (mean MPR 55%).28

Hydroxyurea
Adherence rates in 3 multicenter drug trials of hydroxyurea ranged from 74% to 94%, as measured using pill counts and MEMS caps, respectively.29–31 In these drug efficacy trials, each lasting ≥6 months, participants had study visits every 2 weeks, where a 2-week supply of pills was dispensed and the pills remaining in the bottle from the previous visit were counted. In the study that was not part of a drug effectiveness study, adherence was 49% (5 of 6 refills in previous 6 months) to 85% (clinician report of “often or always adherent”).32,33

Iron Chelation Therapy
In a study of deferasirox, 43% of patients had good adherence by pill counts and 71% by parent report.34 In studies of deferoxamine, adherence rates were

moderate according to the Morisky scale (72%) and patient or parent report of missed doses (43%–57% adherent).35,36

**Prophylactic Antibiotics**

In the 2 studies that compared different administration routes for prophylactic antibiotics, adherence to injections (>90% injections given) was better than to oral medication (40%–44% positive urine test).37,38 Several studies describe gaps in antibiotic use, also known as “uncovered days.” In 1 study, 33.3% of young children had 14 to 30 uncovered days per month.39 In another, there was an average of 27.4 days between fills of a 14-day supply of liquid antibiotics.40 Another found that an average of 60% of a 1-year study period was not covered by antibiotics.41

**Factors Associated With Nonadherence**

Nonadherence among patients with SCD was often related to beliefs about safety and effectiveness of medications or to mistakes administering medications at home (Table 2). Reported mistakes, such as forgetting to give medication40 or being too busy to give medicine,32,42,43 were significantly correlated with poor adherence. In addition, parent knowledge was significantly correlated with better adherence.32,36,42 One study estimates that 30% of variance in adherence can be attributed to health beliefs among patients with SCD, such as beliefs about severity of disease or the burden of using medication.40 Risk factors for nonadherence were found to be additive. Patients with more barriers had worse adherence rates.32 On the contrary, preventive clinic visits may be protective; 1 study found that each preventive visit was associated with an additional 12 days of antibiotic prophylaxis use, based on refill data.41

**Clinical Impact of Nonadherence and Moderate Adherence**

Among hydroxyurea users, nonadherence was associated with reduced fetal hemoglobin levels.32,44 None of the studies of hydroxyurea we reviewed linked moderate adherence to clinical outcomes. Among patients with SCD taking iron chelation, nonadherent patients had less reduction in serum iron than adherent patients (11% vs 44% decline).45 In a study of 15 patients with SCD on deferoxamine, 9 were categorized as moderately adherent; moderately adherent patients had serum ferritin levels that were lower than those of nonadherent patients but not as low as those of adherent patients.42

Three articles described cases of overwhelming sepsis among children with SCD prescribed daily antibiotic prophylaxis.5,46,47 Each described a small number of cases of septicemia; in all but 1, parents reported missing recent antibiotic doses, or patients had a negative urine antibiotic test. It should be noted that adherence rates for those without infections were not reported. There was a significant association between

nonadherence to antibiotics and frequency of sickle cell crises and infection in 1 study. In another study, patients not adherent to antibiotics had a higher rate of emergency department visits (5.5 per year) than adherent patients (2 per year).

**DISCUSSION**

In this systematic review of the medication adherence literature among pediatric patients with SCD, we found that moderate adherence was common. Nonadherence was associated with increased painful crises and increased hospitalizations, yet little information was available about the clinical effects of moderate adherence. Health beliefs (eg, fear of side effects) and factors increasing risk for mistakes (eg, complex medication regimen or more frequent dosing) contributed to nonadherence; barriers to adherence were additive.

We found that medication characteristics, such as route of administration, influenced adherence, consistent with previous literature. Interestingly, adherence to injected antibiotics was markedly better than adherence to oral antibiotics in both studies that compared them. Given that antibiotic prophylaxis is used in children with SCD to prevent life-threatening sepsis, clinicians should consider offering injected antibiotic prophylaxis to families who cannot adhere to oral antibiotics, because the literature indicates that injections ensure fewer unprotected days. Such a decision must be balanced by the consideration that injected antibiotics are more painful than oral antibiotics and that repeated injections may reduce quality of life.

Most studies we reviewed identified a substantial population that was moderately adherent; in studies that measured adherence as a continuous measure, patients took a mean of 40% to 79% of prescribed doses (excluding drug efficacy trials). Such trends can cause physicians to be reluctant to prescribe medications such as hydroxyurea. Hydroxyurea toxicity could develop if the physician is unaware of nonadherence and raises the dosage. The 2 studies we found reporting moderate adherence to hydroxyurea and iron chelation indicated that moderate adherence may have some incremental benefit over poor adherence.

If we accept that moderate adherence is ubiquitous and that some patients have poor adherence, then clinician monitoring of adherence is necessary. In 2010 Drotar suggested that studies are needed to develop and test routine monitoring of adherence to medications among patients with SCD. We recommend combining parent or adolescent report with more objective measures of adherence to optimize monitoring. Report should be obtained in a way that encourages honest responses, such as self-administered written questions at each visit rather than clinician interview. Objective measures for clinicians to routinely monitor adherence should be neither cumbersome nor costly and may include automated collection of pharmacy fill data or pill counts in the office.

To our knowledge, there are few published interventions to improve medication adherence in children with SCD; none are multicenter, and none have significant effect. A randomized trial of a “deferoxamine day camp” for 31 school-age children with SCD did not result in increases in knowledge about deferoxamine or better social support. A randomized trial of parent education, regular social worker contact, and a medication calendar among 45 children was associated with a small but not statistically significant improvement in prophylactic antibiotic adherence. Literature reviews indicate that, among pediatric patients, multicomponent interventions and those with a behavioral component are more likely to be effective than educational interventions alone.

Multicomponent interventions to improve adherence should target different barriers to adherence. Because barriers to adherence are additive, it stands to reason that as each barrier is overcome, adherence may increase. Many barriers were related to health beliefs, such as beliefs about the value of the medicine, not liking to use a needle, or concerns about the adverse effects of medication. Many other barriers were related to mistakes, such as forgetting, not knowing the correct dosage, or difficulty measuring liquid medications.

The existing literature on adherence to medication among people with SCD has important gaps. Larger, multisite studies of medication adherence are needed in children with SCD. In 2010 Drotar highlighted the need for large prospective studies to assess the impact of nonadherence and moderate adherence on biological outcomes. Our review of the literature found few large multisite studies or studies of the impact of moderate adherence. Several studies evaluated adherence as part of an efficacy trial, which does not mimic real-world settings, often using frequent study visits, as in HUG-Kids and BABY HUG, to boost adherence. In some studies, adherence data were not available on the entire population. This limitation introduces potential bias because the more adherent patients may be more likely to participate in adherence measurements. In addition, associations between nonadherence and poor clinical outcomes do not necessarily indicate a causal relationship; prospective studies are needed to distinguish association from causation.

Our systematic review of the literature is subject to several limitations. First, as with any systematic literature review, although our search criteria were designed to be comprehensive, it is possible that we missed relevant articles. Second, we did not include unpublished
literature; publication bias tends to result in the availability of more positive associations. Third, variation in definitions of adherence limits the comparison of data across studies. Finally, variation in population ages, size, and methods to measure adherence prohibits a meta-analysis from being performed and therefore limits interpretation of our findings.

CONCLUSIONS

This review of the literature indicates that many patients with SCD are moderately adherent to medications. Because good adherence is uncommon, we suggest clinicians use routine monitoring of adherence, including parent report and objective measures. Multicomponent interventions should target health beliefs and mistakes in medication administration; educational interventions alone are less likely to be effective. Randomized trials of multicomponent interventions, addressing beliefs and mistakes, are needed to help clinicians optimize outcomes by improving medication adherence.

ACKNOWLEDGMENTS

We thank Dr Jerry Gurwitz for his support of this project.
