**ABSTRACT**

**OBJECTIVES:** To determine whether nutritional intake and medical devices are bisphenol A (BPA) exposure sources among premature infants in the NICU.

**METHODS:** Mothers and their premature infants cared for in the NICU for the past 3 days were recruited for this exposure assessment study. Forty-three mothers contributed 1 nutrition sample (breast milk or formula) to characterize the infant’s intake. Two urine samples (before and after feeding) were collected from each of 55 infants. Medical device use was categorized as “low” or “high” based on the number and invasiveness of devices used. BPA urinary concentrations used as a biomarker to estimate BPA exposure were measured by online solid-phase extraction, high performance liquid chromatography, isotope dilution, tandem mass spectrometry. Nonparametric equivalence tests, intraclass correlations, and hierarchical linear mixed-effects models were conducted.

**RESULTS:** Breast milk and formula samples did not differ in total BPA concentration nor did infants’ median urinary concentration of total BPA before or after feedings. However, the median urinary total BPA concentration among infants who required the use of 4 or more medical devices in the past 3 days was significantly higher (36.6 μg/L) than among infants who required the use of 0 to 3 devices (13.9 μg/L). The calculated BPA exposures are lower than the US Environmental Protection Agency reference dose, but considerably higher (16- to 32-fold) than among infants or children from the general population.

**CONCLUSIONS:** The number of medical devices used in the past 3 days, but not nutritional intake, was positively associated with exposure to BPA. *Pediatrics* 2013;131:483–489

**WHAT’S KNOWN ON THIS SUBJECT:** Bisphenol A (BPA) is an environmental endocrine disruptor that can leach from polycarbonate plastics and epoxy resins, leading to widespread exposure. Fetal and early postnatal periods are particularly vulnerable to exposure to BPA.

**WHAT THIS STUDY ADDS:** This study identified medical devices as a potential source of exposure to BPA among premature infants in the NICU, even when efforts to reduce polycarbonate plastics were taken.
Bisphenol A (BPA) is a synthetic chemical used in the manufacture of polycarbonate plastics and epoxy resins. Polycarbonate plastics are used in consumer products (eg, refillable drinking containers); epoxy resins are used to line beverage and food cans. Diet is considered the major source of exposure to BPA for the general population. Infants and children have a higher estimated daily intake of BPA than adults. The World Health Organization estimated that the mean (95th percentile) BPA intake for breastfed infants between 0 and 6 months of age was 0.3 μg/kg body weight (BW) per day (1.3 μg/kg BW per day), whereas for infants receiving formula from polycarbonate bottles it was 2.4 μg/kg BW per day (4.5 μg/kg BW per day). BPA is rapidly metabolized and excreted in the urine, mainly as a glucuronide conjugate with a half-life of <2 hours. The total (free plus conjugated) BPA urinary concentration is a valid biomarker of BPA exposure. The health effects of free BPA, a weak estrogen, have primarily been studied in animal models, but limited human studies during crucial periods of child development report effects on behavior and executive function in children and shortened anogenital distance in male offspring. Human breast milk is the preferred source of nutrients for low birth weight premature infants, because its use significantly reduces the incidence of necrotizing enterocolitis and late-onset sepsis. However, almost 70% of women who deliver prematurely have difficulty supplying sufficient breast milk to meet their infant's needs; supplementation with formula and the use of human milk fortifier are common and necessary even as pasteurized donor milk has become available.

Medical devices made from polycarbonate plastic such as intravenous administration sets, stopcocks, syringes, intravascular catheters, urinary catheters, gastrointestinal tubes, and cardiopulmonary bypass circuits are sources of exposure to BPA. Data on medical devices as sources of BPA exposure to premature infants in NICU settings are scarce. In 41 premature infants in 2 NICUs, total BPA was detected in 100% of urine samples ranging from 1.6 μg/L to 946 μg/L (median, 28.6 μg/L). On average, infants undergoing high-intensity medical treatment had urinary BPA concentrations 8.75 times higher than infants undergoing low-intensity treatment.

The current study was conducted to determine if nutritional intake and medical devices were sources of BPA exposure in the NICU. In addition, as far as we are aware, there are no studies of the correlation between BPA concentrations in mothers' breast milk and their infants' urine or of the potential correlation of BPA concentrations among multiple-birth siblings.

**METHODS**

**Sample/Participants**

Between November 2009 and March 2010, mother/infant pairs were identified by using a targeted sampling strategy to identify infants with low or high exposure to medical devices. Infants had to spend at least 3 consecutive days in the NICU, and mothers had to be >18 years and able to read and write English. Infants with hepatic or renal failure or genetic abnormalities were excluded. The low-intensity medical device use group included infants who received only nutritional support by bottle-feeding or intermittent gavage via a nasogastric tube or were using nasal oxygen within the preceding 3 days. The high-intensity group included infants with invasive treatments including any vascular catheter, ventilator, continuous positive airway pressure, chest tube, or parenteral nutrition or blood transfusion in addition to bottle-feeding or intermittent gavage. Infants' source of nutrition was identified as exclusively breastfed, formula fed, or a mixture of the 2 and any use of milk fortifiers. Questionnaires and medical records were used to collect information on maternal demographics, lifestyle, pregnancy history, perinatal medical care and interventions, medications, and medical history. Infant data included gestational age and weight, head circumference, length, Apgar scores, serum bilirubin levels, and kidney, liver, and thyroid functions if available. The type (breast milk or formula) and method of nutrition (gavage, bottle, or breast) was recorded, along with the use and amount of milk fortifiers or parenteral nutrition, as was oxygen usage and method of delivery, and the use of other medical devices and equipment. Sample collection devices were prescreened for BPA. Maternal milk was expressed by mechanical pumping and frozen in BPA-free storage containers provided by the hospital. BPA-free breast pump disposable devices (Medela Inc, McHenry, IL) were routinely made available to mothers by the hospital, although some mothers could have used different systems. Before use, milk was thawed in a "warm to touch" tap water bath. One milliliter of maternal breast milk or formula from the milk storage container was obtained immediately before the feeding by using a plastic pipette. Samples were stored in 10-mL polypropylene Cryovials at 4°C for up to 8 hours and then stored at −80°C.

Infant urine samples were collected by positioning 2 or 3 100% cotton balls within the diaper, immediately before...
a feeding and after the feeding at the time of the next scheduled cluster of care (up to 3–4 hours). Wet cotton balls were placed in a plastic specimen cup and, in general, were stored for <2 hours at 4°C until the urine could be extracted by manual squeezing by using nitrile gloves. The urine was then pipetted into a polypropylene Cryovial and stored at −80°C. Urine specific gravity (SG) was measured by using the Atago digital handheld “pocket” SG refractometer (PAL-10S model, Bellevue, WA), which was calibrated before use. One field blank from cotton balls soaked in deionized water was collected and analyzed for each day’s biological samples.

**Analytical Methods for the Quantification of BPA in Urine and Nutrition Samples**

Total urinary concentrations of BPA and total and free concentrations of BPA in nutrition samples were determined as described before. In brief, the conjugated species of BPA in 100 μL of urine or milk were hydrolyzed enzymatically. After hydrolysis (the hydrolysis step was omitted for the determination of the concentration of free species), samples were acidified; BPA was preconcentrated by online solid-phase extraction, separated from other components by high-performance liquid chromatography, and detected by atmospheric pressure chemical ionization (urine) or atmospheric pressure photoionization (nutrition samples), tandem mass spectrometry. The limits of detection (LODs) were 0.4 μg/L (urine) and 0.3 μg/L (milk). The method accuracy ranged from 98% to 113% (urine) and 90% to 108% (milk) at 4 concentrations. The coefficients of variation of repeated measures of low- and high-concentration quality-control materials, prepared with spiked pooled human urine (~3 μg/L and ~20 μg/L) or milk (~9 μg/L and ~23 μg/L), ranged from 6.3% to 8.3% (milk) and 6% to 17% (urine). Quality-control materials were analyzed along with standards (range, 0.1–100 μg/L), reagent blank, infants’ samples, and field blanks. Urinary BPA concentrations were adjusted for dilution by using SG.

**Calculated Daily BPA Exposure**

Premature infants in this study generally had normal renal function and hydration; therefore, the predicted urine output is 38 mL/kg per day. Daily BPA exposure was calculated as described previously and comparisons were made with other study populations.

**RESULTS**

**Subjects**

Participants included 43 mothers and their infants (n = 55), who were predominately white (60% and 71%, respectively) (Table 1). There were 10 sets of multiple births with 70% of the deliveries by cesarean delivery, 58% of infants were very preterm (<32 weeks), whereas 49% were very low birth weight (<1500 g) (Table 1). The median age at birth was 30 weeks (range, 24–38 weeks), and the median postconception age of the infants at the time of urine collection was 34 weeks (range, 27–40 weeks).

**Urinary BPA Concentrations**

Of the anticipated 110 urine specimens, 104 were collected, including pre- and postfeeding samples from 49 infants, and a single sample from 6 infants. Total BPA was detected in all infants with median urinary concentrations before and after feeding of 17.2 and 18.3 μg/L, respectively (Table 2).

**Nutritional BPA Concentration**

Thirty infants (55%) were exclusively fed breast milk, 24 (44%) were exclusively fed formula, and 1 received a mixture of breast milk and formula. All breast milk and 92% of formula samples had detectable concentrations of total BPA; free BPA was detected less frequently (29%, breast milk; 54%, formula) (Table 2). Two breast milk samples had concentrations of total (222 and 296 μg/L) and free (189 and 252 μg/L) BPA that were at least 1 order of magnitude higher than the concentrations in other nutritional samples. The next highest BPA concentration was 10.8 and 6.1 μg/L for total and free BPA, respectively. These 2 statistical outlier samples were not included in further analyses.

DUTY et al

486

Urinary BPA concentrations were lower (2.6 [0.9, 4.4] g/L; 24.8 [13.2, 4.4] g/L) than among 255 infants (14.3 g/L; 15.4 g/L). Therefore, source of nutrition was ignored to explore the quantitative estimate of nutritional BPA intake (μg/kg BW per day) with cross-feed urine BPA concentrations. There were no cross-feed differences in urinary BPA (P = .15); therefore, the mean of the 2 urine samples per infant was used to test for differences between medical device use groups.

Cross-feed Nutritional Influence

There was a 0.9 μg/L difference in median urinary BPA concentration across feeding (17.2 μg/L prefeed and 18.3 μg/L postfeed; P = .37). The cross-feed change in median BPA was —0.45 μg/L (P = .47) in infants breastfed and 2.4 μg/L (P = .13) in formula-fed infants. In mixed-effects models, after adjustment for gestational age, birth weight, and time since feeding, there was no difference in urinary BPA across feedings based on source of nutrition (P = .32). Therefore, source of nutrition was ignored to explore the quantitative estimate of nutritional BPA intake (μg/kg BW per day) with cross-feed urinary BPA concentrations. There were no cross-feed differences in urinary BPA (P = .15); therefore, the mean of the 2 urine samples per infant was used to test for differences between medical device use groups.

Medical Device Use

Using a priori medical device use groups ("high" and "low"), the high-group infants had median (25th, 75th percentile) urinary BPA concentrations (15.5 [13.3, 40.7] μg/L) greater than the low-group infants (13.2 [8.4, 38.2] μg/L; P value for difference = .13). On secondary analysis evaluating individual medical devices, on average, infants requiring nasal oxygen, continuous positive airway pressure, or a nasogastric tube had significantly higher urinary BPA concentrations than infants not requiring these devices (see Table 3). In addition, the median (25th, 75th percentile) urinary BPA concentrations among 11 infants using 4 or more medical devices (36.6 [17.2, 47.3] μg/L) was significantly higher (P = .01) than among 44 infants using 0 to 3 devices (13.7 [9.2, 35.1] μg/L).

Calculated Daily BPA Exposure

Calculated exposures are presented in Table 4 for the median, 95th percentile, and maximum urinary total BPA concentrations. Comparisons with other populations are highlighted.

Variance Apportionment for Clustered Data

Urine concentrations collected after successive feedings had high temporal reliability; the intraclass correlation coefficient for unadjusted urinary BPA concentrations was 0.81 (95% confidence interval, 0.69–0.88), whereas for SG-adjusted BPA it was 0.65 (0.49–0.79). Between-mother variability was the highest (68% for uncorrected BPA, 58% for SG-corrected BPA), followed by within infant (19% for uncorrected BPA, 34% for SG-corrected BPA) and within mother/between infant (13% for uncorrected BPA, 8% for SG-corrected BPA) variability.

Prematurity and Birth Weight

Median urinary BPA concentrations differed significantly by gestational age group (4.3 μg/L at >37 weeks, 12.4 μg/L at 32–36 weeks, 34.2 μg/L at <32 weeks; P < .001) and by birth weight (9.2 μg/L among normal weight, 12.7 μg/L for low birth weight, and 36.6 μg/L for very low birth weight, P < .001). Birth weight and gestational age were highly correlated (Spearman correlation coefficient = 0.92;

cantly associated with gender and
high medical device use.

**DISCUSSION**

In the current study, all infants had
detectable urinary concentrations of
total BPA, ranging from 2.0 to 196 μg/L.
The median urinary BPA concentration
in this group of premature infants was
considerably higher (17.2 μg/L) than in
healthy term infants aged 1 to 5
months (<0.45 μg/L) without known
BPA exposure.21 Although immaturity
of phase II metabolism may account
for some of the association of urinary
BPA concentrations with prematurity,
premature infants have the ability to
conjugate BPA.16 Interestingly, medical
devices, but not nutritional intake, were
positively associated with urinary BPA
concentrations. On average, premature
infants requiring ≥4 medical devices
had urinary total BPA concentrations 1.6
times higher (95% confidence
interval, 1.01–2.58; \( P = .045 \)) than
those using 0 to 3 devices.

PEDIATRICS Volume 131, Number 3, March 2013

Downloaded from by guest on June 9, 2017
times higher than those requiring fewer devices independent of their gestational age, gender, or nutritional intake. Respiratory devices were associated with higher urinary BPA concentrations than other devices. These findings suggest that medical devices were an important source of BPA exposure for these infants.

Median BPA concentrations among the infants in this study were 36% lower than those reported by Calafat et al. Calafat also reported a larger magnitude of association between high and low medical device use (8.75-fold versus 1.6-fold observed in our study), but adjustments were only made for infant gender and institution. Adjustment for urinary dilution, nutritional intake, infant gender, and gestational age as done in our analysis provides for a more precise estimate of association with medical device use. It is also likely that concerted efforts over the past years to eliminate or decrease the use of plastics containing BPA in devices and feeding equipment in this particular NICU have led to a decrease in overall BPA exposure. In the model presented, prematurity and medical device use accounted for ~30% and 10%, respectively, of the variability in urinary BPA. It seems reasonable to suspect that prematurity could have accounted for some of the association between medical devices and urinary BPA observed in the Calafat et al study.

In the general population, diet is considered the primary source of BPA exposure, but that was not true in this medically complex NICU population. Similar to findings by World Health Organization, the calculated mean (95th percentile) exposure to BPA of exclusively breast milk fed infants was 0.23 μg/kg BW per day (1.1 μg/kg BW per day), and the estimated mean (95th percentile) exposure of formula fed infants was 0.16 μg/kg BW per day (0.61 μg/kg BW per day). The mean total BPA urinary concentration among the exclusively formula-fed infants (13.1 μg/L) was lower than those exclusively fed breast milk (23.3 μg/L), a difference that did not reach statistical significance.

In the current study, multiple-birth infants, who have similar dietary sources, treatment levels, and surroundings, have more similar urinary BPA concentrations than infants from different mothers. Understanding that most of the variability came from between-family and very little from within-infant will aid in making appropriate power and sample size calculations in the design of future studies that involve clustering of infants within family.

CONCLUSIONS

This study provided detailed information on the duration of use of specific medical devices and estimation of the nutritional intake of BPA from either maternal milk or formula. Urinary BPA concentrations were statistically higher as the number of medical devices used over the 3 days before evaluation increased, but they were not associated with the nutritional sources (breast milk or formula). Although median BPA exposures calculated from urinary concentrations were 16- to 32-fold higher for neonates in the NICU in comparison with children in the general population or healthy infants, they were still below the US Environmental Protection Agency reference dose (RfD) (dose below which no adverse health effects should result from a lifetime of exposure). However, it is important to keep in mind that, although BPA concentrations were below the RfD, there is ongoing controversy regarding potential health risks of low-dose (ie, below RfD) exposures to BPA. Finally, the degree of prematurity and gender remained strong significant independent predictors of urinary BPA concentrations even after adjustment for device use and nutritional exposure, indicating the need for additional research into other potential determinants in the NICU including the microenvironment of the isolette.

ACKNOWLEDGMENTS

We acknowledge the technical assistance of X. Zhou, R. Hennings, and T. Jia for measuring the urinary concentrations of BPA.
