Trends in Metabolic Syndrome Severity and Lifestyle Factors Among Adolescents

Arthur M. Lee, BS, a Matthew J. Gurka, PhD, b Mark D. DeBoer, MD, MSc, MCR a

BACKGROUND AND OBJECTIVES: Childhood metabolic syndrome (MetS) is a risk factor for adverse outcomes later in life. Our goal was to identify temporal trends among US adolescents in the severity of MetS, its individual components, and factors related to diet and physical activity.

METHODS: We analyzed 5117 participants aged 12 to 19 from NHANES. We used regression analysis of individual waves of data, 1999 to 2012. MetS severity was calculated using a gender- and race/ethnicity-specific MetS severity z score.

RESULTS: There was a linear trend of decreasing MetS severity in US adolescents from 1999 to 2012 (P = .030). This occurred despite a trend of increasing BMI z score (P = .005); instead, the decrease in MetS severity appeared to be due to trends in increasing high-density lipoprotein (HDL; P < .0001) and decreasing triglyceride (P = .0001) levels. In considering lifestyle factors, there was no change in physical activity over the time period. Regarding dietary patterns, total calorie consumption and carbohydrate consumption were positively associated with HDL levels and negatively associated with triglyceride levels, whereas unsaturated fat consumption exhibited the opposite associations. Consistent with these associations, there was a trend of decreasing total calorie consumption (P < .0001), decreasing carbohydrate consumption (P < .0001), and increasing unsaturated fat consumption (P = .002).

CONCLUSIONS: The healthier trend of declining MetS severity in adolescents appeared to be due to favorable increases in HDL and decreases in fasting triglyceride measurements. These were in turn associated with favorable changes in dietary patterns among US adolescents. Future studies should investigate the causality of dietary differences on changes in MetS severity in adolescents.

WHAT’S KNOWN ON THIS SUBJECT: The prevalence of the metabolic syndrome (MetS) has recently appeared to be decreasing in adults. There has been a plateauing of obesity in adolescents, but temporal trends of the MetS prevalence and severity in this age range are unclear.

WHAT THIS STUDY ADDS: The severity of MetS decreased in adolescents from 1999 to 2012 because of decreases in abnormalities in high-density lipoprotein cholesterol and triglycerides. Over the same time frame, there were improvements in dietary intake, potentially related to these improvements.
The metabolic syndrome (MetS) is characterized by central obesity, high fasting glucose, high fasting triglycerides, high blood pressure (BP), and low high-density lipoprotein (HDL). Traditional MetS criteria, such as those developed for adults by the National Cholesterol Education Program Adult Treatment Panel (ATP-III)\(^1\) or adolescent adaptations,\(^2\) define MetS diagnosis as presence of at least 3 abnormalities among these 5 clinical components. MetS is a priority to characterize because it is a significant risk factor for cardiovascular disease (CVD) and type 2 diabetes mellitus (T2DM).\(^3\)–\(^7\)

However, the binary nature of the ATP-III MetS diagnostic criteria has limitations in epidemiologic studies. The ATP-III criteria give no indication of disease severity, limiting their ability to track MetS severity over time.\(^8\) The ATP-III criteria also do not account for differences in MetS by race/ethnicity and gender, resulting in MetS underdiagnosis in specific groups, such as non-Hispanic blacks.\(^9\)–\(^14\) This is a concern because non-Hispanic-black individuals have higher rates of T2DM and CVD despite low rates of ATP-III MetS diagnosis.\(^15\)–\(^19\)

The recently developed MetS Severity Score (MetS \(z\) score) calculator addresses the epidemiologic limitations of the ATP-III criteria.\(^20,21\) This tool accounts for differences in MetS by race/ethnicity and gender. It is reflective of severity, with a higher score correlating to more severe MetS and increased odds for associated risk factors.\(^20,21\) Childhood MetS \(z\) score elevations are associated with risk for adult T2DM and CVD.\(^22,23\)

Recent reports have shown a decrease in the prevalence of MetS among US adults, attributed to increased awareness and pharmaceutical treatment of the individual components of MetS.\(^24,25\) The goal of the current study was to investigate for trends in MetS prevalence (by using modified ATP-III criteria) and severity (using MetS \(z\) scores\(^20\)) in US adolescents. Our hypothesis was that the decreasing trends observed in adults would not be observed in US adolescents because of the persisting childhood obesity epidemic.\(^26,27\) Our secondary goal was to evaluate for trends in physical activity and overall dietary factors that may be related to any changes in MetS. These studies may help gauge how the United States is responding to childhood MetS.

**METHODS**

We examined participant data from the Centers for Disease Control and Prevention (CDC) NHANES (1999–2012). NHANES is a cross-sectional, national, stratified, multistage probability survey conducted in 2-year waves with randomly selected noninstitutionalized US civilians. NHANES oversampled racial/ethnic minority groups as well as those at or below 130% of the federal poverty level. Calculated sample weights accounted for this oversampling as well as different response rates among groups to ensure nationally representative estimates. This study was approved by the National Center for Health Statistics ethics review board. Participants provided informed consent. Laboratory and clinical measurements were obtained by using controlled equipment and protocols.\(^24,28,29\) Fasting blood samples were obtained from participants who attended morning sessions at CDC NHANES mobile examination centers. HDL was measured by direct immunoassay. Fasting glucose was measured by using an enzyme hexokinase method. Triglycerides were measured by using a timed-end point method. BMI \(z\) scores were calculated according to the US CDC 2000 growth reference adjusting for age and gender.\(^30\) High BP was defined as systolic or diastolic BP exceeding the 90th percentile for gender, age, and height.\(^31\)

We examined data from 5117 adolescents aged 12 to 19 with complete data regarding MetS and not meeting exclusion criteria. Participants were excluded for the following conditions that may affect participants’ laboratory measures in a way that is unlikely to be associated with the lifestyle factors we were evaluating: nonfasting status, pregnancy, active hepatitis B infection \((n = 8)\), physician-diagnosed diabetes \((n = 66)\), or current use of antidiabetic or antihyperlipidemic medication \((n = 42)\). Participants taking antihypertensives were classified as having elevated BP \((n = 69)\).

There are no official criteria for evaluating MetS in children and adolescents. Multiple sets of criteria have been proposed and used.\(^32,33\) We elected to use the adolescent adaptation of the ATP-III criteria because these are based on the NCEP ATP-III definition of MetS in adults.\(^1\) MetS was defined as having at least 3 of the following: BMI \(z\) score \(\geq 1.645\), fasting glucose \(\geq 100\ \text{mg/dL}\), fasting triglycerides \(\geq 110\ \text{mg/dL}\), HDL \(\leq 40\ \text{mg/dL}\), and systolic or diastolic BP exceeding the 90th percentile for height, age, and gender.\(^2\) MetS severity was calculated by using the Pediatric MetS \(z\) Score (http://mets.health-outcomes-policy.ufl.edu/calculator).\(^20\) This set of scores was formulated previously by using data from non-Hispanic white, non-Hispanic black, and Hispanic adolescents aged 12 to 19 years participating in NHANES 1999 to 2010. We used confirmatory factor analysis on individual gender- and racial/ethnic group, generating equations to calculate a \(z\) score estimating the severity of MetS. These scores thus use the same clinical measurements as the ATP-III criteria, but with race/ethnicity- and gender-specific loading factors to account for the unequal contributions.
to MetS of each clinical factor across different groups. These scores highly correlate with other surrogate markers of MetS risk, including high-sensitivity C-reactive protein, uric acid, and the homeostasis model of insulin resistance. In a longitudinal study of 629 children and adolescents followed into adulthood, MetS z score correlated with 27- and 37-year later risk of developing CVD and T2DM.

Dietary intake was determined from a 24-hour food recall administered by a trained dietary interviewer by using a 4-step multipass approach in the mobile examination center on the examination day. Interview data were processed and coded based on individual foods and portion sizes to determine specific nutrient intake based on US Department of Agriculture’s National Nutrient Database for Standard Reference. Specific food group consumption was reported as percentage of calories accounted by specific food group.

The equations were as follows: % total energy from carbohydrates = (4 * grams of carbohydrates)/total calories, % total energy from fats = (9 * grams of fat)/total calories, % total energy from protein = (7 * grams of protein)/total calories.

From 2007 to 2012, physical activity was assessed as minutes per week of moderate to vigorous physical recreational activity per day. Participants were first asked if they did any vigorous/moderate-intensity sports, fitness, or recreational activities that cause large increase in breathing or heart rate, such as running or basketball for at least 10 minutes continuously. If they answered yes, they were further questioned for how many minutes per typical day they do these activities.

Statistical significance was defined as P < .05. Statistical analysis was performed using SAS (version 9.4, Cary, NC). SAS survey procedures were used to account for the complex survey design to obtain population-based estimates. Linear regression was used to estimate means of quantitative measurements across each NHANES period and assess for temporal linear trends. Fasting plasma triglyceride data were log transformed for regression analysis and back-transformed for data presentation. Temporal linear trends in prevalence of clinical abnormalities were assessed with logistic regression analyses.

### RESULTS

#### Prevalence and Trends in MetS

We analyzed data from 5117 adolescents with complete MetS data, including 1490 non-Hispanic whites, 1655 non-Hispanic blacks, and 2018 Hispanics (Table 1). The overall prevalence of ATP-III MetS in this time period was 9.83%. This overall prevalence varied by gender (males 10.90%, females 6.29%, P < .0001) and race/ethnicity (Hispanics 9.97%, non-Hispanic whites 9.04%, and non-Hispanic blacks 4.45%, P < .0001).

Overall mean (SD) MetS z score in this time period was −0.05 (0.02). Mean MetS z score varied by race: Hispanics 0.04 (0.03), non-Hispanic whites −0.04 (0.02), and non-Hispanic blacks −0.19 (0.03).

Tables 2 and 3 and Fig 1 display overall temporal trends in MetS and its individual components, along with variations by gender and race/ethnicity. Overall, there were temporal trends of decreasing MetS z score (P = .030) and fasting triglyceride measurements (P = .0001). There were further temporal trends of increasing BMI z score (P = .005) and HDL levels (P < .0001). There were no significant trends in overall fasting glucose and mean systolic BP measurements. There were no associated trends in the prevalence of ATP-III MetS and obesity. There were decreasing trends in the proportion of children with high fasting triglycerides (P < .0013) and low HDL prevalence (P < .0001).

In a sensitivity analysis, we repeated the linear regression analyses assessing trends in MetS z score and the laboratory values versus time in a sample that included adolescents with diagnosed diabetes or taking antidiabetic or antihyperlipidemic agents. There were no significant differences with the previous analyses when these previously excluded adolescents were included (data not shown).

### Discussion

**Adolescents Lifestyle Trends Among US**

Given the changes in fasting triglycerides, HDL, BMI, score, and improvements in overall MetS and MetS severity among adolescents, we next evaluated for potentially related trends in dietary intake and physical activity.

Overall temporal trends in calorie and unsaturated fat consumption, decreasing total calorie consumption, decreasing carbohydrate consumption, increasing unsaturated fat consumption, decreasing and increasing MetS severity among adolescents, we next evaluated for potentially related trends in dietary intake and physical activity.

The decreasing trend in MetS (P = .05) was secondary to the increasing trend in MetS severity among adolescents, we next evaluated for potentially related trends in dietary intake and physical activity.

Slope estimates are reported with 95% confidence intervals in parentheses. All reported values were obtained from survey procedures based on weighted numbers. *< .05.

As alluded to earlier, we were unable to attribute the trends in MetS severity and its individual factors to physical activity factors. Our analysis of physical activity data was limited because NHANES did not have a consistent variable assessing physical activity from 1999 to 2012. Additionally, there are questions about the validity of quantifying adolescent physical activity data. There have been findings that adolescent self-reported physical activity data are significantly correlated to accelerometer data. However, a adolescent accelerometer data also has limitations with respect to bias and generizability.

There were additional limitations to our study. The ATP-III criteria lead to underdiagnosis of MetS in specific racial/ethnic groups. This could result in an overall underestimate of MetS prevalence in the US adolescent population, particularly among African American adolescents. However, other sets of MetS criteria, which differ...
FIGURE 1
Trends in prevalence and measurements of MetS and its components versus time. Individual means and 95% confidence interval bars are shown for each sampling period. Regression lines are shown with 95% confidence bands shaded. $P$ values are reported for nonzero trends. For prevalence values, slope is reported as change in percentage per sampling period. For measurements, slope is reported as change in measurement unit per sampling period. There were significant decreasing trends of low HDL and hypertriglyceridemia prevalence. There were significant decreasing trends in MetS $z$ score and fasting plasma triglycerides. There were significant increasing trends in BMI $z$ score and HDL.

There were significant decreasing trends in total calorie consumption and percentage of calories accounted for by carbohydrates. There was a significant increasing trend in percentage of calories accounted for by unsaturated fats.
largely in individual component cutoffs, have also had racial/ethnic discrepancies noted.\textsuperscript{15} We do not believe the use of a different set of MetS criteria would have had a significant effect on our results regarding trends in MetS diagnosis. Instead, we attempted to overcome the epidemiologic limitations by use of a MetS severity score that uniquely addresses differences in MetS by race/ethnicity. These MetS severity z scores have been validated, although they currently lack absolute cutoffs that correspond to particular risk for outcomes. There are current and future research efforts directed at achieving this goal. We were unable to assess causality due to the cross-sectional nature of NHANES. We correlated trends in MetS with lifestyle factors, but this can only be interpreted as association with unclear links to causality. Future studies should be directed at investigating the causality of lifestyle factors in improvements of MetS severity. Diet quality assessment was limited by its dependence on participant accurate reporting and bias.

CONCLUSIONS
This study has importance in that it is nationally representative for the US adolescent population, is novel in its temporal assessment of MetS severity, and explores possible lifestyle factors contributing to population health trends. These data further confirm the need for research, public health, and clinical collaboration in combatting childhood MetS.

An error occurred in the print edition of the article by Lee et al, titled “Trends in Metabolic Syndrome Severity and Lifestyle Factors Among Adolescents” published in the March 2016 issue of Pediatrics (2016;137[3];doi:10.1542/peds.2015-3177). On page 27, a sentence in the abstract mistakenly stated: “Regarding dietary patterns, total calorie consumption and carbohydrate consumption were positively associated with HDL levels and negatively associated with triglyceride levels.” The sentence should have read: “Regarding dietary patterns, total calorie consumption and carbohydrate consumption were positively associated with triglyceride levels and negatively associated with HDL levels, whereas unsaturated fat consumption exhibited the opposite associations.” The online edition of this article has been corrected.
