As such, the diagnosis and management of AOM has a significant impact on the health of children, cost of providing care, and overall use of antibacterial agents. The illness also generates a significant social burden and indirect cost due to time lost from school and work. The estimated direct cost of AOM was $1.96 billion in 1995. In addition, the indirect cost was estimated to be $1.02 billion.1 During 1990 there were almost 25 million visits made to office-based physicians in the United States for otitis media, with 809 antibacterial prescriptions per 1000 visits, for a total of more than 20 million prescriptions for otitis media–related antibacterials. Although the total number of office visits for otitis media decreased to 16 million in 2000, the rate of antibacterial prescribing was approximately the same (802 antibacterial prescriptions per 1000 visits for a total of more than 13 million prescriptions).2–4 An individual course of antibacterial therapy can range in cost from $10 to more than $100.

There has been much discussion recently as to the necessity for the use of antibacterial agents at the time of diagnosis in children with uncomplicated AOM. Although in the United States the use of antibacterial agents in the management of AOM has been routine, in some countries in Europe it is common practice to treat the symptoms of AOM initially and only institute antibacterial therapy if clinical improvement does not occur. For the clinician, the choice of a specific antibacterial agent has become a key aspect of management. Concerns about the rising rates of antibacterial resistance and the growing costs of antibacterial prescriptions have focused the attention of the medical community and the general public on the need for judicious use of antibacterial agents. Greater resistance among many of the pathogens that cause AOM has fueled an increase in the use of broader-spectrum and generally more expensive antibacterial agents.

It is the intent of this guideline to evaluate the published evidence on the natural history and management of uncomplicated AOM and to make recommendations based on that evidence to primary care clinicians including pediatricians, family physicians, physician assistants, nurse practitioners, and emergency department physicians as well as otolaryngologists. The scope of the guideline is the diagnosis and management of uncomplicated AOM in children from 2 months through 12 years of age without signs or symptoms of systemic illness unre-
lated to the middle ear. It applies only to the otherwise healthy child without underlying conditions that may alter the natural course of AOM. These conditions include, but are not limited to, anatomic abnormalities such as cleft palate, genetic conditions such as Down syndrome, immunodeficiencies, and the presence of cochlear implants. Also excluded are children with a clinical recurrence of AOM within 30 days or AOM with underlying chronic otitis media with effusion (OME).

METHODS
To develop the clinical practice guideline on the management of AOM, the American Academy of Pediatrics (AAP) and American Academy of Family Physicians (AAFP) convened the Sub-committee on Management of Acute Otitis Media, a working panel composed of primary care and subspecialty physicians. The subcommittee was cochaired by a primary care pediatrician and a family physician and included experts in the fields of general pediatrics, family medicine, otology, epidemiology, infectious disease, and medical informatics. All panel members reviewed the AAP policy on conflict of interest and voluntary disclosure and were given an opportunity to present any potential conflicts with the subcommittee’s work.

The AAP and AAFP partnered with the Agency for Healthcare Research and Quality (AHRQ) and the Southern California Evidence-Based Practice Center to develop the evidence report, which served as a major source of data for these practice guideline recommendations. Specific clinical issues addressed in the AHRQ evidence report were the 1) definition of AOM, 2) natural history of AOM without antibacterial treatment, 3) effectiveness of antibacterial agents in preventing clinical failure, and 4) relative effectiveness of specific antibacterial regimens. The AHRQ report focused on children between 4 weeks and 18 years of age with uncomplicated AOM seeking initial treatment. Outcomes included the presence or absence of signs and symptoms within 48 hours, at 3 to 7 days, 8 to 14 days, 15 days to 3 months, and more than 3 months and the presence of adverse effects from antibacterial treatment. Southern California Evidence-Based Practice Center project staff searched Medline (1966 through March 1999), the Cochrane Library (through March 1999), HealthSTAR (1975 through March 1999), International Pharmaceutical Abstracts (1970 through March 1999), CINAHL (1982 through March 1999), BIOSIS (1970 through March 1999), and Embase (1980 through March 1999). Additional articles were identified by review of reference lists in proceedings, published articles, reports, and guidelines. Studies relevant to treatment questions were limited to randomized, controlled trials. For natural history, prospective and retrospective comparative cohort studies were included also. A total of 3461 titles were identified initially for additional review. Of these, 2701 were excluded, and 760 required article review. Finally, 72 English-language and 2 foreign-language articles were reviewed fully. Results of the literature review were presented in evidence tables and published in the final evidence report.

New literature about otitis media is being published constantly. Although the systematic review done by the AHRQ could not be replicated with new literature, members of the Subcommittee on Management of Acute Otitis Media reviewed additional articles published through September 2003. Articles were nonsystematically evaluated for quality of methodology and importance of results. Articles used in the AHRQ review also were reevaluated for their quality. Conclusions were based on the consensus of the subcommittee after the review of newer literature and reevaluation of the AHRQ evidence. Of significance is that the literature includes relatively few cases of uncomplicated AOM in children older than 12 years. The subcommittee therefore limited this guideline to children from 2 months through 12 years of age.

The evidence-based approach to guideline development requires that the evidence in support of a policy be identified, appraised, and summarized and that an explicit link between evidence and recommendations be defined. Evidence-based recommendations reflect the quality of evidence and the balance of benefit and harm that is anticipated when the recommendation is followed. The AAP definitions of evidence-based recommendations are shown in Table 1.

A draft version of this practice guideline underwent extensive peer review by committees and sections within the AAP, reviewers appointed by the AAFP, outside organizations, and other individuals identified by the subcommittee as experts in the field. Members of the subcommittee were invited to distribute the draft to other representatives and committees within their specialty organizations. The resulting comments were reviewed by the subcommittee and, when appropriate, incorporated into the guideline.

RECOMMENDATION 1
To diagnose AOM the clinician should confirm a history of acute onset, identify signs of middle-ear effusion (MEE), and evaluate for the presence of signs and symptoms of middle-ear inflammation. (This recommendation is based on observational studies and a preponderance of benefit over risk; see Table 2.)

<table>
<thead>
<tr>
<th>Statement</th>
<th>Definition</th>
<th>Implication</th>
</tr>
</thead>
<tbody>
<tr>
<td>Strong recommendation</td>
<td>A strong recommendation in favor of a particular action is made when the anticipated benefits of the recommended intervention clearly exceed the harms (as a strong recommendation against an action is made when the anticipated harms clearly exceed the benefits) and the quality of the supporting evidence is excellent. In some clearly identified circumstances, strong recommendations may be made when high-quality evidence is impossible to obtain and the anticipated benefits strongly outweigh the harms.</td>
<td>Clinicians should follow a strong recommendation unless a clear and compelling rationale for an alternative approach is present.</td>
</tr>
<tr>
<td>Recommendation</td>
<td>A recommendation in favor of a particular action is made when the anticipated benefits exceed the harms, but the quality of evidence is not as strong. Again, in some clearly identified circumstances, recommendations may be made when high-quality evidence is impossible to obtain but the anticipated benefits outweigh the harms.</td>
<td>Clinicians would be prudent to follow a recommendation but should remain alert to new information and sensitive to patient preferences.</td>
</tr>
<tr>
<td>Option</td>
<td>Options define courses that may be taken when either the quality of evidence is suspect or carefully performed studies have shown little clear advantage to one approach over another.</td>
<td>Clinicians should consider the option in their decision-making, and patient preference may play a substantial role.</td>
</tr>
<tr>
<td>No recommendation</td>
<td>No recommendation indicates that there is a lack of pertinent published evidence and that the anticipated balance of benefits and harms is unclear.</td>
<td>Clinicians should be alert to new published evidence that clarifies the balance of benefit versus harm.</td>

</table>
TABLE 2. Definition of AOM

A diagnosis of AOM requires 1) a history of acute onset of signs and symptoms, 2) the presence of MEE, and 3) signs and symptoms of middle-ear inflammation.

Elements of the definition of AOM are all of the following:
1. Recent, usually abrupt, onset of signs and symptoms of middle-ear inflammation and MEE
2. The presence of MEE that is indicated by any of the following:
   a. Bulging of the tympanic membrane
   b. Limited or absent mobility of the tympanic membrane
   c. Air-fluid level behind the tympanic membrane
   d. Otorrhea
3. Signs or symptoms of middle-ear inflammation as indicated by either
   a. Distinct erythema of the tympanic membrane or
   b. Distinct otalgia (discomfort clearly referable to the ear[s] that results in interference with or precludes normal activity or sleep)

Children with AOM usually present with a history of rapid onset of signs and symptoms such as otalgia (or pulling of the ear in an infant), irritability in an infant or toddler, otorrhea, and/or fever. These findings, other than otorrhea, are nonspecific and frequently overlap those of an uncomplicated viral upper respiratory infection. In a prospective survey among 354 children who visited a physician for acute respiratory illness, fever, earache, and excessive crying were present frequently (90%) in those with AOM. However, these symptoms also were prominent among children without AOM (72%). Other symptoms of a viral upper respiratory infection, such as cough and nasal discharge or stuffiness, often precede or accompany AOM and are nonspecific also. Accordingly, clinical history alone is poorly predictive of the presence of AOM, especially in younger children.

The presence of MEE is commonly confirmed with the use of pneumatic otoscopy but can be supplemented by tympanometry and/or acoustic reflectometry. MEE also can be demonstrated directly by tympanocentesis or the presence of fluid in the external auditory canal as a result of tympanic membrane perforation.

Visualization of the tympanic membrane with identification of an MEE and inflammatory changes is necessary to establish the diagnosis with certainty. To visualize the tympanic membrane adequately it is essential that cerumen obscuring the tympanic membrane be removed and that lighting is adequate. For pneumatic otoscopy, a speculum of proper shape and diameter must be selected to permit a seal in the external auditory canal. Appropriate restraint of the child to permit adequate examination may be necessary also.

The findings on otoscopy indicating the presence of MEE and inflammation associated with AOM have been well defined. Fullness or bulging of the tympanic membrane is often present and has the highest predictive value for the presence of MEE. When combined with color and mobility, bulging is also the best predictor of AOM. Reduced or absent mobility of the tympanic membrane during performance of pneumatic otoscopy is additional evidence of fluid in the middle ear. Opacification or cloudiness, other than that caused by scarring, is also a consistent finding and is caused by edema of the tympanic membrane. Redness of the tympanic membrane caused by inflammation may be present and must be distinguished from the pink erythematous flush evoked by crying or high fever, which is usually less intense and remits as the child quiets down. In bullous myringitis, blisters may be seen on the tympanic membrane. When the presence of middle-ear fluid is difficult to determine, the use of tympanometry or acoustic reflectometry can be helpful in establishing a diagnosis.

A major challenge for the practitioner is to discriminate between OME and AOM. OME is more common than AOM. OME may accompany viral upper respiratory infections, be a prelude to AOM, or be a sequela of AOM. When OME is identified mistakenly as AOM, antibacterial agents may be prescribed unnecessarily. Clinicians should strive to avoid a false-positive diagnosis in children with middle-ear discomfort caused by eustachian tube dysfunction and retraction of the tympanic membrane or when acute viral respiratory infection is superimposed on chronic preexisting MEE.

The diagnosis of AOM, particularly in infants and young children, is often made with a degree of uncertainty. Common factors that may increase uncertainty include the inability to sufficiently clear the external auditory canal of cerumen, a narrow ear canal, or inability to maintain an adequate seal for successful pneumatic otoscopy or tympanometry. An uncertain diagnosis of AOM is caused most often by inability to confirm the presence of MEE. Acoustic reflectometry can be helpful, because it requires no seal of the canal and can determine the presence of middle-ear fluid through only a small opening in the cerumen. When the presence of middle-ear fluid is questionable or uncertain, a diagnosis of AOM may be considered but cannot be confirmed. Although every effort should be made by the clinician to differentiate AOM from OME or a normal ear, it must be acknowledged that, using all available tools, uncertainty will remain in some cases. Efforts to improve clinician education must be increased to improve diagnostic skills and thereby decrease the frequency of an uncertain diagnosis. Ideally, instruction in the proper examination of the child’s ear should begin with the first pediatric rotation in medical school and continue throughout postgraduate training. Continuing medical education should reinforce the importance of and retrain the clinician in the use of pneumatic otoscopy. By including the degree of certainty into the formation of a management plan, the everyday challenge of pediatric examinations is incorporated into decision-making.

A certain diagnosis of AOM meets all 3 of the criteria: rapid onset, presence of MEE, and signs and symptoms of middle-ear inflammation. The clinician should maximize diagnostic strategies, particularly to establish the presence of MEE, and should consider the certainty of diagnosis in determining management. Clinicians may wish to discuss the degree of diagnostic certainty with parents/caregivers at the time of initial AOM management.
randomized, controlled trials with limitations and a rela-
tions policy statement 1454

DIAGNOSIS AND MANAGEMENT OF ACUTE OTITIS MEDIA

children 6 months to 2 years of age with nonsevere
illness at presentation and an uncertain diagnosis and
to children 2 years of age and older without severe
symptoms at presentation or with an uncertain diagu-
nosis. In these situations, observation provides an
opportunity for the patient to improve without anti-
bacterial treatment. The association of age younger
than 2 years with increased risk of failure of watchful
waiting and the concern for serious infection among
children younger than 6 months influence the deci-
sion for immediate antibacterial therapy. Conse-
quently, the panel recommends an age-stratified ap-
proach that incorporates these clinical considerations
along with the certainty of diagnosis (Table 4).

Placebo-controlled trials of AOM over the past 30
years have shown consistently that most children do
well, without adverse sequelae, even without anti-
bacterial therapy. Between 7 and 20 children must be
treated with antibacterial agents for 1 child to derive
benefit.34–36 By 24 hours, 61% of children have de-
creased symptoms whether they receive placebo or

RECOMMENDATION 2
The management of AOM should include an as-
essment of pain. If pain is present, the clinician should
recommend treatment to reduce pain. (This is a strong
recommendation based on randomized, clinical trials with
limitations and a preponderance of benefit over risk.)
Many episodes of AOM are associated with pain.23
Although pain is an integral part of the illness, cli-
nicians often see otalgia as a peripheral concern not
requiring direct attention.24 The AAP published the
policy statement “The Assessment and Management of
Acute Pain in Infants, Children, and Adolescents”25 to
assist the clinician in addressing pain in the
context of illness. The management of pain, es-
specially during the first 24 hours of an episode of
AOM, should be addressed regardless of the use of
antibacterial agents.

Various treatments of otalgia have been used, but
none has been well studied. The clinician should
select a treatment based on a consideration of bene-
fits and risks and, wherever possible, incorporate
parent/caregiver and patient preference (Table 3).

RECOMMENDATION 3A
Observation without use of antibacterial agents in
children 6 months to 2 years of age with nonsevere
illness at presentation and an uncertain diagnosis and
to children 2 years of age and older without severe
symptoms at presentation or with an uncertain diag-
nosis. In these situations, observation provides an
opportunity for the patient to improve without anti-
bacterial treatment. The association of age younger
than 2 years with increased risk of failure of watchful
waiting and the concern for serious infection among
children younger than 6 months influence the deci-
sion for immediate antibacterial therapy. Conse-
quently, the panel recommends an age-stratified ap-
proach that incorporates these clinical considerations
along with the certainty of diagnosis (Table 4).

Placebo-controlled trials of AOM over the past 30
years have shown consistently that most children do
well, without adverse sequelae, even without anti-
bacterial therapy. Between 7 and 20 children must be
treated with antibacterial agents for 1 child to derive
benefit.34–36 By 24 hours, 61% of children have de-
creased symptoms whether they receive placebo or

RECOMMENDATION 3A
Observation without use of antibacterial agents in
children 6 months to 2 years of age with nonsevere

* Observation is an appropriate option only when follow-up can be ensured and antibacterial agents started if symptoms persist or worsen. Nonsevere illness is mild otalgia and fever <39°C in the past 24 hours. Severe illness is moderate to severe otalgia or fever ≥39°C. A certain diagnosis of AOM meets all 3 criteria: 1) rapid onset, 2) signs of MEE, and 3) signs and symptoms of middle-ear inflammation.
antibacterial agents. By 7 days, approximately 75% of children have resolution of symptoms. The AHRQ evidence-report meta-analysis showed a 12.3% reduction in the clinical failure rate within 2 to 7 days of diagnosis when ampicillin or amoxicillin was prescribed, compared with initial use of placebo or observation (number needed to treat: 8).

In 1990 the Dutch College of General Practitioners adopted a guideline for the management of AOM that recommended treating symptoms without antibacterial agents for 24 hours (for those 6–24 months old) or 72 hours (for those more than 24 months) and adding antibacterial agents if no improvement is evident at reassessment. A 1999 revision to this early guideline does not distinguish the younger age group for special consideration. Although this guideline has been widely adopted in The Netherlands, its use in other countries requires considerations of the availability of access to care for follow-up and the presence of an adult who can adequately monitor the child’s course. Although there are no controlled studies that address the question of whether the Dutch guideline has resulted in more complications after AOM, van Buchem et al found that only 2.7% of 4860 Dutch children older than 2 years given only symptomatic treatment developed severe illness, defined by persistent fever, pain, or discharge after 3 to 4 days. Only 2 children developed mastoiditis. One case of mastoiditis was present at initial assessment, and the other developed within the first week and resolved promptly with oral antibacterial agents.

Randomized trials of observation with symptomatic treatment have been few. A recent randomized trial in general practice in the United Kingdom compared providing immediate antibacterial therapy with delaying antibacterial agents for 72 hours in children aged 6 months to 10 years. Seventy-six percent of children in the delayed-treatment group never required antibacterial agents. Seventy percent of the delayed-antibacterial group were symptomatically better at 3 days, whereas 86% of the immediate-treatment group were better. Immediate use of antibacterial agents was associated with approximately 1-day-shorter illness and one-half teaspoon of acetaminophen consumption but no difference in school absence, pain, or distress scores. Among children with fever or vomiting on day 1, those receiving immediate antibacterial agents were 21% less likely to have distress on day 3. In children without fever or vomiting, immediate antibacterial agents decreased distress on day 3 by only 4%. This study, however, was limited because of the use of imprecise criteria for the diagnosis of AOM and the use of low doses of amoxicillin (125 mg, 3 times a day, for 7 days for all patients regardless of weight) in the treatment group.

The likelihood of recovery without antibacterial therapy differs depending on the severity of signs and symptoms at initial examination. Kaleida et al divided patients into severe and nonsevere groups based on degree of fever, a scoring system based on duration and severity of pain or apparent discomfort, and estimated parental anxiety. In the nonsevere group, initial treatment failure occurred in 3.8% more children who received placebo rather than amoxicillin. In the severe group of children, the initial failure rate on placebo plus myringotomy was 23.5% versus an initial failure rate of 9.6% on amoxicillin alone (a difference of 13.9%).

Several investigators report poorer outcomes in younger children. A greater number of penicillin-resistant strains of pneumococci are isolated in those younger than 18 months, compared with older children, and are associated with an increased bacteriologic failure rate in children younger than 2 years. The study by Kaleida et al also shows a greater initial clinical failure rate (9.8%) in children younger than 2 years than in those older than 2 years (5.5%) who were in the placebo group.

Routine antibacterial therapy for AOM is often cited as the main reason for the decrease in the incidence of mastoiditis in the antibacterial era. By the 1950s, mastoiditis (frequent in the pre-antibacterial-agent era) had decreased dramatically. Although some have expressed concern about a possible resurgence, such concern is not supported by published data.

The AHRQ evidence report on AOM concluded that mastoiditis is not increased with initial observation, provided that children are followed closely and antibacterial therapy is initiated in those who do not improve. Pooled data from 6 randomized trials and 2 cohort studies showed comparable rates of mastoiditis in children (0.59%) who received initial antibacterial therapy and children (0.17%) who received placebo or observation (P = .212). External validity might be limited, however, because some trials excluded very young children or those with severe illness.

Recently published case series of pediatric mastoiditis show that acute mastoiditis is most common in infants and young children and can be the presenting sign of AOM in a patient with no prior middle-ear disease. Routine antibacterial therapy for AOM is not an absolute safeguard against mastoiditis and other complications, because most cases (36%–87%) have received prior antibacterial therapy.

Van Zuijlen et al compared national differences in acute mastoiditis rates from 1991 to 1998 for children 14 years of age or younger. Incidence rates were higher in The Netherlands, Norway, and Denmark (in which antibacterial agents are not necessarily given on initial diagnosis of AOM) than in the United Kingdom, Canada, Australia, and the United States (in which antibacterial agents are prescribed in more than 96% of cases). However, despite initial use of antibacterial agents more than twice as often in Norway and Denmark than in The Netherlands, mastoiditis rates in all 3 countries were comparable.

Thus current evidence does not suggest a clinically important increased risk of mastoiditis in children when AOM is managed only with initial symptomatic treatment without antibacterial agents. Clinicians should remain aware that antibacterial-agent treatment might mask mastoiditis signs and symp-
Although bacteremia may accompany AOM, particularly in children with a temperature higher than 39°C, there is little evidence that routine antibacterial treatment for otitis media prevents bacterial meningitis. In a study of 4860 children with AOM who did not receive antibacterial therapy, no cases of bacterial meningitis were observed. However, in a study involving 240 children between 6 and 24 months of age, 1 child in the placebo group was subsequently diagnosed as having meningitis. In another report, positive blood cultures were equally common in children with bacterial meningitis regardless of whether they received preadmission treatment with antibacterials for AOM (77% and 78%). Thus, as with mastoiditis, the incidence of meningitis in those with AOM is unlikely to be influenced by initial treatment of AOM with antibacterial agents.

The incidence of invasive pneumococcal disease has decreased since the introduction of the protein-polysaccharide conjugate vaccine (PPV7). There has been a 69% decline in children younger than 2 years between 1998–1999 and 2001. The decline in this age group for invasive disease caused by vaccine serotypes during that period was 78%. How this will affect the risk of AOM-associated invasive pneumococcal disease is not known yet.

As noted by Dagan and McCracken, studies comparing efficacy of different antibacterial agents or placebo compared with antibacterial therapy often have significant design flaws that may influence the outcome of the studies. Methodologic considerations include enrollment criteria, sample size, diagnostic criteria, dosing regimens, definition and timing of outcome criteria, age, severity of symptoms, race, immune system, compliance, virulence and resistance of the infecting organism, duration of antibacterial therapy, and the presence of an underlying respiratory infection. One of the most important issues among the design characteristics of the studies of otitis media is the definition of AOM used in the individual investigations. If studies that evaluate the impact of antibacterial therapy on the clinical course of children with AOM have weak definitions of AOM (that allow the inclusion of children who are more likely to have OME than AOM), recipients of placebo will not respond significantly differently from those who receive antibacterial therapy.

Given the sum of the available evidence, clinicians may consider observation with symptomatic treatment as an option for initial management of selected children with AOM. If the “observation option” is used, the clinician should share with parents/caregivers the degree of diagnostic certainty and consider their preference. The potential of antibacterial therapy at the initial visit to shorten symptoms by 1 day in 5% to 14% of children can be compared with the avoidance of common antibacterial side effects in 5% to 10% of children, infrequent serious side effects, and the adverse effects of antibacterial resistance. When considering this option, the clinician should verify the presence of an adult who will reliably observe the child, recognize signs of serious illness, and be able to provide prompt access to medical care if improvement does not occur. If there is worsening of illness or if there is no improvement in 48 to 72 hours while a child is under observation, institution of antibacterial therapy should be considered. Reexamination may be warranted if discussion with the parents raises concern as to the degree of illness.

If a decision is made to treat with an antibacterial agent, the clinician should prescribe amoxicillin for most children. (This recommendation is based on randomized, clinical trials with limitations and a preponderance of benefit over risk.)

When amoxicillin is used, the dose should be 80 to 90 mg/kg per day. (This option is based on extrapolation from microbiologic studies and expert opinion, with a preponderance of benefit over risk.)

If a decision is made to treat with antibacterial agents, there are numerous medications that are clinically effective. The choice of first-line treatment should be based on the anticipated clinical response as well as the microbiologic flora likely to be present. The justification to use amoxicillin as first-line therapy in most patients with AOM relates to its general effectiveness when used in sufficient doses against susceptible and intermediate resistant pneumococci as well as its safety, low cost, acceptable taste, and narrow microbiologic spectrum. In patients who have severe illness (moderate to severe otalgia or fever of 39°C or higher) and in those for whom additional coverage for β-lactamase–positive Haemophilus influenzae and Moraxella catarrhalis is desired, therapy should be initiated with high-dose amoxicillin-clavulanate (90 mg/kg per day of amoxicillin component, with 6.4 mg/kg per day of clavulanate in 2 divided doses). This dose has sufficient potassium clavulanate to inhibit all β-lactamase–producing H influenzae and M catarrhalis.

Many clinical studies comparing the effectiveness of various antibacterial agents in the treatment of AOM do not carefully define standard criteria for diagnosis of AOM at entry or for improvement or
cure at follow-up. Another way to measure the outcome of treatment of AOM with various antibacterial agents is to assess bacteriologic efficacy. Although this does not provide a one-to-one correlation with clinical effectiveness, there is a definite concordance between the two. Children who experience a bacteriologic cure improve more rapidly and more often than children who experience bacteriologic failure. Carlin et al showed an 86% agreement between clinical and bacteriologic response. Dagan et al showed that 91% of clinical failures at or before day 10 were culture-positive at days 4 to 5. If we use bacteriologic cure as a surrogate for clinical efficacy, there is strong evidence that drugs that achieve bacteriologic concentrations that are able to eradicate pathogens from the middle-ear fluid are the preferred selection.

Numerous studies have shown that the common pathogens in AOM are Streptococcus pneumoniae, nontypeable H influenzae, and M catarrhalis. S pneumoniae has been recovered from the middle-ear fluid of approximately 25% to 50% of children with AOM, H influenzae from 15% to 30%, and M catarrhalis from approximately 3% to 20%. There is some evidence that the microbiology of AOM may be changing as a result of routine use of the heptavalent pneumococcal vaccine. Block et al showed an increase in H influenzae from 39% to 52% of isolates in children 7 to 24 months of age with AOM and a decrease in S pneumoniae from 49% to 34% between 1992–1998 and 2000–2003. Viruses, including respiratory syncytial virus, rhinovirus, coronavirus, parainfluenza, adenovirus, and enterovirus, have been found in respiratory secretions and/or MEE in 40% to 75% of AOM cases and in MEE without bacteria in 5% to 22% of cases and may be responsible for many cases of apparent antibacterial agent “failure.” In approximately 16% to 25% of cases of AOM, no bacterial or viral pathogen can be detected in MEE.

Currently approximately 50% of isolates of H influenzae and 100% of M catarrhalis derived from the upper respiratory tract are likely to be β-lactamase-positive nationwide. Between 15% and 50% (average: 30%) of upper respiratory tract isolates of S pneumoniae are also not susceptible to penicillin; approximately 50% of these are highly resistant to penicillin (minimum inhibitory concentration: 2.0 μg/mL or higher), and the remaining 50% are intermediate in resistance (minimum inhibitory concentration: between 0.1 and 1.0 μg/mL). The mechanism of penicillin resistance among isolates of S pneumoniae is not associated with β-lactamase production but rather an alteration of penicillin-binding proteins. This phenomenon, which varies considerably according to geographic location, results in resistance to penicillins and cephalosporins.

Data from early studies of patients with AOM show that 19% of children with S pneumoniae and 48% with H influenzae cultured on initial tympanocentesis who were not treated with antibacterial agents cleared the bacteria at the time of a second tympanocentesis 2 to 7 days later. Estimates are that approximately 75% of children infected with M catarrhalis also experience bacteriologic cure, based on resolution after treatment with an antibacterial agent to which it is not susceptible (amoxicillin). Only S pneumoniae that are highly resistant to penicillin will not respond to conventional doses of amoxicillin. Accordingly, approximately 80% of children with AOM will respond to treatment with high-dose amoxicillin, including many caused by resistant pneumococci. The higher dose will yield middle-ear fluid levels that exceed the minimum inhibitory concentration of all S pneumoniae that are intermediate in resistance to penicillin and many, but not all, highly resistant S pneumoniae. Risk factors for the presence of bacterial species likely to be resistant to amoxicillin include attendance at child care, recent receipt (less than 30 days) of antibacterial treatment, and age younger than 2 years.

If the patient is allergic to amoxicillin and the allergic reaction was not a type I hypersensitivity reaction (urticaria or anaphylaxis), cefdinir (14 mg/kg per day in 1 or 2 doses), cefpodoxime (10 mg/kg per day, once daily), or cefuroxime (30 mg/kg per day in 2 divided doses) can be used. In cases of type I reactions, azithromycin (10 mg/kg per day for 5 days) is the preferred choice. Table 5 shows the results of observational and randomized trials of selected therapies for AOM.
day on day 1 followed by 5 mg/kg per day for 4 days as a single daily dose) or clarithromycin (15 mg/kg per day in 2 divided doses) can be used in an effort to select an antibacterial agent of an entirely different class. Other possibilities include erythromycin-sulfisoxazole (50 mg/kg per day of erythromycin) or sulfamethoxazole-trimethoprim (6–10 mg/kg per day of trimethoprim). Alternative therapy in the penicillin-allergic patient who is being treated for infection that is known or presumed to be caused by penicillin-resistant *S pneumoniae* is clindamycin at 30 to 40 mg/kg per day in 3 divided doses. In the patient who is vomiting or cannot otherwise tolerate oral medication, a single dose of parenteral ceftriaxone (50 mg/kg) has been shown to be effective for the initial treatment of AOM.98,99

The optimal duration of therapy for patients with AOM is uncertain. Studies comparing standard duration of treatment (10 days) to short-duration treatment (1–7 days) were often characterized by limitations including inadequate sample size (therefore having low or limited statistical power), few or no children younger than 2 years, exclusion of otitis-prone children, lack of standardized or stringent criteria for the diagnosis of AOM or for improvement or cure, use of an antibacterial medication that had less than optimal efficacy against common middle-ear pathogens, use of lower than recommended dosage of a medication, and lack of analysis of outcome by age.100 Not surprisingly, the results of these studies were variable. Several more recent studies have been reported that addressed the issue of duration of therapy.101–105 The results favoring standard 10-day therapy have been most significant in children younger than 2 years and suggestive of increased efficacy in those 2 to 5 years of age. Thus, for younger children and for children with severe disease, a standard 10-day course is recommended.106 For children 6 years of age and older with mild to moderate disease, a 5- to 7-day course is appropriate.

**RECOMMENDATION 4**

If the patient fails to respond to the initial management option within 48 to 72 hours, the clinician must reassess the patient to confirm AOM and exclude other causes of illness. If AOM is confirmed in the patient initially managed with observation, the clinician should begin antibacterial therapy. If the patient was initially managed with an antibacterial agent, the clinician should change the antibacterial agent. (This recommendation is based on observational studies and a preponderance of benefit over risk.)

When antibacterial agents are prescribed for AOM, the time course of clinical response should be 48 to 72 hours. With few exceptions, the first 24 hours of therapy are characterized by a stabilization of the clinical condition. Early during this period the patient may actually worsen slightly. In the second 24 hours, the patient should begin to improve. If initially febrile, the patient is expected to defervesce within 48 to 72 hours. Irritability should improve, and sleeping and eating patterns should begin to normalize.97 If the patient is not improved by 48 to 72 hours, either another disease is present or the therapy that has been chosen was not adequate. When observation has been the chosen management and spontaneous improvement has not been noted by 48 to 72 hours, antibacterial therapy is indicated to limit the duration of further illness.

The patient should be given clear instructions at the initial visit as to when and how to communicate continuation or worsening of signs and symptoms to the clinician to expedite a change in treatment.

Antibacterial-agent choice after initial failure of observation or first-line antibacterial therapy should be based on the likely pathogen(s) present and on clinical experience. If the patient was treated with initial observation, amoxicillin should be started at a dose of 80 to 90 mg/kg per day. For patients who have severe illness (moderate to severe otalgia or temperature of 39°C or higher42), in those for whom additional coverage for β-lactamase-positive *H influenzae* and *M catarrhalis* is desired, and for those who had been treated initially with amoxicillin and did not improve, high-dose amoxicillin-clavulanate (90 mg/kg per day of amoxicillin component, with 6.4 mg/kg per day of clavulanate in 2 divided doses)76 should be used. Alternatives in patients with a history of a non–type I allergic reaction to penicillins are cefdinir, cefpodoxime, or cefuroxime.88 In cases of type I reactions, alternatives are azithromycin, clarithromycin, erythromycin-sulfisoxazole, or sulfamethoxazole-trimethoprim. Ceftriaxone (50 mg/kg per day), given for 3 consecutive days either intravenously or intramuscularly, can be used in children with vomiting or in other situations that preclude administration of oral antibacterial agents. In the treatment of AOM unresponsive to initial antibacterial therapy, a 3-day course of ceftriaxone has been shown to be better than a 1-day regimen.99 Although trimethoprim-sulfamethoxazole and erythromycin-sulfisoxazole have traditionally been useful as first- and second-line therapy for patients with AOM, recent pneumococcal surveillance studies indicate that resistance to these 2 combination agents is substantial.90,95 Therefore, when patients fail to improve while receiving amoxicillin, neither trimethoprim-sulfamethoxazole105 nor erythromycin-sulfisoxazole is optimal for antibacterial therapy.

A patient who fails amoxicillin-potassium clavulanate should be treated with a 3-day course of parenteral ceftriaxone because of its superior efficacy against *S pneumoniae*, compared with alternative oral antibacterials.91,99 If AOM persists, tympanocentesis should be recommended to make a bacteriologic diagnosis. If tympanocentesis is not available, a course of clindamycin may be considered for the rare case of penicillin-resistant pneumococcal infection not responding to the previous regimens. If the patient still does not improve, tympanocentesis with Gram-stain, culture, and antibacterial-agent sensitivity studies of the fluid is essential to guide additional therapy. Table 6 summarizes antibacterial options.

Once the patient has shown clinical improvement, follow-up is based on the usual clinical course of AOM. Persistent MEE after resolution of acute symptoms is common and should not be viewed as a need for active therapy. Two weeks after an episode of AOM, 60% to 70% of children have MEE, decreasing
OME must be differentiated clinically from AOM and requires additional monitoring but not antibacterial therapy. Assurance that OME resolves is particularly important for children with cognitive or developmental delays that may be impacted adversely by transient hearing loss associated with MEE.

**RECOMMENDATION 5**

Clinicians should encourage the prevention of AOM through reduction of risk factors. (This recommendation is based on strong observational studies and a preponderance of benefits over risks.)

A number of factors associated with early or recurrent AOM are not amenable to change, for example, genetic predisposition, premature birth, male gender, Native American/Inuit ethnicity, family history of recurrent otitis media, presence of siblings in the household, and low socioeconomic status. A number of factors associated with early or recurrent AOM are not amenable to change, for example, genetic predisposition, premature birth, male gender, Native American/Inuit ethnicity, family history of recurrent otitis media, presence of siblings in the household, and low socioeconomic status. A number of factors associated with early or recurrent AOM are not amenable to change, for example, genetic predisposition, premature birth, male gender, Native American/Inuit ethnicity, family history of recurrent otitis media, presence of siblings in the household, and low socioeconomic status.

During infancy and early childhood, reducing the incidence of respiratory tract infections by altering child care center attendance patterns can reduce the incidence of recurrent AOM significantly. The implementation of breastfeeding for at least the first 6 months also seems to be helpful against the development of early episodes of AOM. Avoiding supine bottle feeding (“bottle propping”), reducing or eliminating pacifier use in the second 6 months of life, and eliminating exposure to passive tobacco smoke have been postulated to reduce the incidence of AOM in infancy; however, the utility of these interventions is unclear.

Immunoprophylaxis with killed influenza vaccines has demonstrated more than 30% efficacy in prevention of AOM during the respiratory illness season. Most of the children in these studies were older than 2 years. A controlled study among infants and toddlers 6 to 23 months of age failed to demonstrate any efficacy of killed vaccine in preventing AOM. Pneumococcal conjugate vaccines have proven effective in preventing vaccine-serotype pneumococcal otitis media, but their overall benefit is small, with only a 6% reduction in the incidence of AOM.

Medical office visits for otitis were reduced by 7.8% and antibiotic prescriptions by 5.7% in a large clinical practice after introduction of the pneumococcal conjugate vaccine. Respiratory syncytial virus, parainfluenza virus, and adenovirus vaccines currently under development hold additional promise for prevention of ear infections.

**RECOMMENDATION 6**

No recommendations for complementary and alternative medicine (CAM) for treatment of AOM are made based on limited and controversial data.

Increasing numbers of parents/caregivers are using various forms of nonconventional treatment for their children. The types of treatments used can differ depending on the ethnic background and belief system of the family and the availability of alternative medicine in a particular community. Treat-
ments that have been used for AOM include homeopathy, acupuncture, herbal remedies, chiropractic treatments, and nutritional supplements.130 Many physicians ask parents, caregivers, or older children if they are using medicines, supplements, or other means to maintain health or treat specific conditions;131 however, parents/caregivers are often reluctant to tell their physicians that they are using...
complementary or alternative treatments. Although most treatments are harmless, some are not. Some treatments can have a direct and dangerous effect, whereas others may interfere with the effects of conventional treatments. Clinicians should become more informed about CAM, ask whether they are being used, and be ready to discuss potential benefits or risks.

To date there are no studies that conclusively show a beneficial effect of alternative therapies used for AOM. Recent interest in the use of CAM has led to research efforts to investigate its efficacy. It is difficult to design and conduct studies on certain forms of CAM because of the unique nature of the treatment. Any study conducted will need to show proof of effectiveness of a specific therapy when compared with the natural history of AOM. Conclusions regarding CAM cannot be made until research evidence is available.

**FUTURE RESEARCH**

Despite the voluminous literature about AOM, there still are many opportunities for future research to continue to clarify the accurate diagnosis and most effective management of this common condition. Most important is that future studies address concerns regarding the quality and applicability of many studies in AOM. Future studies should use standardized criteria for diagnosis, outcome, and severity of illness; increase sample size, which in general has been too limited to identify small but significant differences in clinical outcome; include children younger than 2 years and older than 12 years; use doses of medication shown to achieve adequate levels in the middle ear to treat the target organisms successfully; and stratify outcomes by age and severity of illness. In addition, studies done in limited geographic areas must be replicated in other areas to ensure generalizability.

Some of the studies that should be considered include:

- Additional validation of standard definitions of AOM
- New or improved technologies for objective diagnosis of MEE
- Efficacy of education programs to improve clinician diagnostic skills
- Additional studies on pain management including topical agents, CAM, and role of tympanocentesis/myringotomy in pain management
- Large population-based studies on the benefits and risks of the “observation option” looking at antibacterial use; bacterial resistance; incidence of adverse events; long-term effects on hearing; persistence of MEE; and parent, patient, and clinician satisfaction
- Continued development of new antibacterial agents to address potential changes in resistance patterns of organisms responsible for AOM (studies on new agents must be appropriately designed and have adequate sample size to show clinical efficacy equal to or better than current agents)
- Randomized, controlled trials on duration of treatment in all age groups

Additional studies on potential measures to prevent AOM

SUMMARY
This clinical practice guideline provides evidence-based recommendations for the definition and management of AOM in children from 2 months through 12 years of age without signs or symptoms of systemic illness unrelated to the middle ear. It emphasizes accurate diagnosis and adherence to a consistent definition of AOM. Management of the pain associated with AOM is identified as an essential aspect of care. An option to observe a select group of children with AOM with symptomatic therapy for 48 to 72 hours is supported by evidence and may potentially lead to decreased use of antibacterial agents. If a decision is made to treat with an antibacterial agent, amoxicillin at a dose of 80 to 90 mg/kg per day is recommended as the initial antibacterial agent of choice for most children. Additional guidance is given for choosing an antibacterial agent when an alternative to amoxicillin is indicated. Also, addressed is evidence related to the prevention of AOM and the role of CAM in the treatment of AOM. The recommendations are summarized in Fig. 1.

CONCLUSIONS
1. Recommendation: To diagnose AOM the clinician should confirm a history of acute onset, identify signs of MEE, and evaluate for the presence of signs and symptoms of middle-ear inflammation.
2. Strong recommendation: The management of AOM should include an assessment of pain. If pain is present, the clinician should recommend treatment to reduce pain.
3A. Option: Observation without use of antibacterial agents in a child with uncomplicated AOM is an option for selected children based on diagnostic certainty, age, illness severity, and assurance of follow-up.
3B. Recommendation: If a decision is made to treat with an antibacterial agent, the clinician should prescribe amoxicillin for most children.
   Option: When amoxicillin is used, the dose should be 80 to 90 mg/kg per day.
4. Recommendation: If the patient fails to respond to the initial management option within 48 to 72 hours, the clinician must reassess the patient to confirm AOM and exclude other causes of illness. If AOM is confirmed in the patient initially managed with observation, the clinician should begin antibacterial therapy. If the patient was initially managed with an antibacterial agent, the clinician should change the antibacterial agent.
5. Recommendation: Clinicians should encourage the prevention of AOM through reduction of risk factors.
6. No recommendation: There is insufficient evidence to make a recommendation regarding the use of CAM for AOM.
